False Alarms and Missed Emergencies: An Evaluation of the Famine Early Warning Systems Network

October 2026

Working draft — not for citation

Abstract

The U.S.-funded Famine Early Warning Systems Network (FEWS NET) forecasts food crises in about 30 countries, at a cost of about $45 million a year. We score its 2011–2024 forecasts against independent IPC and Cadre Harmonisé assessments and link them to humanitarian funding. Only 4 percent of new emergencies arrived with no warning of at least Crisis, but four months ahead FEWS NET forecast just 42 percent of them as emergencies. Its forecasts add to what donors could otherwise know, and funding follows them. But phases of food insecurity say little about lives. In Somalia's scheduled nutrition surveys, FEWS NET's forecasts do not predict measured child malnutrition (correlation 0.10), while the previous survey does (0.66); elsewhere, one phase goes with 1–3 points of acute malnutrition and little or no change in death rates, far less than the IPC's reference bands assume. Recalibrated accordingly, FEWS NET's distinctive information averts a death for every $46,000–150,000 of its budget, well below the most cost-effective charities. Its written reports and market prices add little to its forecasts. Nutrition surveys predict malnutrition far better; if treatment followed them, a round of Somalia's surveys would avert deaths at roughly $1,200–2,200 each.

1 Introduction

In August 2010, the Famine Early Warning Systems Network warned that failing rains would push southern Somalia into crisis. By March 2011 it was warning of possible famine. Famine was declared in July 2011, and an estimated 258,000 people died between 2010 and 2012, about half of them young children (Salama et al., 2012; Checchi and Robinson, 2013). The post-mortems agreed that the warnings had been timely and right; the response was not (Hillbruner and Moloney, 2012). Fourteen years later the question has flipped. In late January 2025, during the freeze on U.S. foreign assistance, FEWS NET went offline. It had been publishing maps and forecasts for 32 countries; it came back in stages from August 2025, under the State Department, and its long-run funding remains uncertain (Devex, 2025; NPR, 2026). Somalia 2011 shows that a warning system can be right and still not save lives. The question now is whether it is worth paying for at all.

This paper asks what FEWS NET's warnings are worth, using the data FEWS NET itself publishes and the independent assessments that run alongside it. We organize the evaluation around the two ways a warning system can fail. A *Type II error* is a missed emergency: a crisis that arrives without warning. A *Type I error* is a false alarm: a warned crisis that never comes. The two errors are not symmetric in what they reveal. If warnings work — if they bring aid that prevents the crisis — a correct warning looks like a false alarm. Aid can turn a true positive into an apparent Type I error, but it cannot create a Type II error. So observed false alarms overstate how often FEWS NET was wrong, while observed misses are a lower bound on how often it failed to see a crisis coming. This asymmetry, and FEWS NET's own judgments about where aid is holding back a crisis, shape the whole analysis.

We combine four data sources: (i) every FEWS NET current-situation map and medium-term forecast for 16,684 areas in 37 countries, 2011–2024; (ii) the Cadre Harmonisé in West Africa and the multi-agency IPC elsewhere, which publish their own area classifications and projections; (iii) humanitarian funding commitments from OCHA's Financial Tracking Service; and (iv) local rainfall, political violence and food prices — the raw signals a donor could watch without FEWS NET.

Our first finding is that FEWS NET rarely misses a crisis entirely but often misjudges its severity. Of 1,562 areas that newly entered Emergency (Phase 4 on the five-phase IPC scale), 85 percent were already in Crisis (Phase 3), and only 4 percent had no forecast of at least Crisis in the preceding eight months. Yet FEWS NET forecast Emergency for only 42 percent of these areas four months ahead and 22 percent eight months ahead. For comparison, it forecast Emergency for 1.3 percent of areas that did not tip over. Its warnings carry real signal; they mostly arrive late and at one phase too low.

Second, about half of FEWS NET's emergency warnings did not come true, but FEWS NET itself attributes many of these to aid. Of 4,084 area-months forecast four to eight months ahead to be in Emergency, 46 percent were, 30 percent ended in Crisis with FEWS NET's flag that humanitarian assistance was keeping the area at least one phase better, and 20 percent ended in Crisis without that flag. Taking FEWS NET's judgment at face value, about a quarter of emergency

warnings were genuine false alarms. Two checks temper that reading. Nearly half of the flagged "averted" cases were already flagged before the warning, so the flag often describes ongoing aid rather than a response to the warning. And we find no sign that warnings come true less often when funding to the country then rises unusually fast, which is what aid-prevented crises would produce.

Third, FEWS NET knows things that other sources do not. We build two benchmarks for what a donor could know without it: one from rainfall, conflict and food prices, and one that adds the latest official IPC or Cadre Harmonisé analysis. Without FEWS NET, donors would usually have had only the first: just 25 percent of FEWS NET's area-rounds had an official analysis from the previous eight months. Scored against the next independent assessment, adding FEWS NET's maps and forecasts raises the area under the ROC curve for areas tipping into Crisis from 0.79 to 0.85 over the raw-data benchmark, and from 0.84 to 0.86 over the benchmark with official analyses. In a head-to-head with the official projections for the same areas and seasons, FEWS NET catches somewhat fewer new crises (37 versus 42 percent) but raises fewer false alarms (7 versus 12 percent), and its forecast predicts the next official analysis even after controlling for the official projection.

Fourth, money follows FEWS NET's distinctive information. Across countries, humanitarian funding tracks FEWS NET's maps closely. Within a country over time, funding follows its forecasts rather than its current maps. Splitting the forecast into the part predictable from the country, the season, rainfall, conflict and prices, and FEWS NET's own contribution, only the latter predicts funding: a 10 percentage point rise in the share of a country's areas that FEWS NET forecasts to be in Crisis, beyond what that information predicts, comes with 12 percent more humanitarian funding and 33 percent more food and nutrition funding over the next six months. A partial check within Somalia and Sudan, using the small share of aid that can be located by district, finds no sign that located aid follows FEWS NET's own information, though that slice of aid is too small to settle the question.

Fifth, phases of food insecurity are a poor guide to malnutrition and death. To turn phases into lives, evaluations, including earlier drafts of this one, use the IPC's reference table, which ties each phase to bands of crude death rates and child acute malnutrition. We know of no study that systematically tests those bands against survey-measured outcomes across areas. In Somalia, where nutrition surveys run on a fixed schedule twice a year, FEWS NET's forecasts do not predict measured child malnutrition (a correlation of 0.10), while the zone's survey six months earlier does (0.66). Within a zone, one phase worse goes with about 0.8 points more acute malnutrition and 0.12 more deaths per 10,000 people per day, against 5–10 points and 0.45–0.75 deaths in the IPC bands. Surveys elsewhere, the IPC's own malnutrition classifications and the excess deaths estimated in recent Somali droughts point the same way.

Sixth, we combine these pieces into a rough benefit-cost calculation. We take FEWS NET at its word about where aid is holding back a crisis, translate one phase into deaths using the evidence-based calibration, and credit FEWS NET only with the aid that follows its distinctive information — what it says beyond each country's usual situation, the season, rainfall, conflict and prices.

On that basis FEWS NET averts 290–970 deaths a year, at $46,000–150,000 per death averted, an order of magnitude more than the $3,000–5,500 of the most cost-effective charities (GiveWell, 2024b). With the IPC bands instead, the figure would be $3,700–15,000. FEWS NET does better measured in food insecurity, keeping a person out of Emergency for a year for every $400–1,100.

Seventh, we ask which parts of FEWS NET carry its value, since funders can pay for pieces rather than the whole. A pilot that turns 502 of FEWS NET's written reports for Somalia, Ethiopia and Sudan into data, using a large language model, finds that the text adds almost nothing to its maps. Market prices add little to forecasts either, from WFP or from FEWS NET's own price monitoring. New surveys move FEWS NET's maps upward, but even when their results are reassuring, which suggests that the decision to send a survey team, rather than what it finds, carries the signal. Finally, we ask whether paying for more surveys would pass the test FEWS NET fails. Surveys are the only good source on malnutrition and mortality. If treatment programmes placed resources by survey results, which they do only partly today, a round of Somalia's scheduled surveys would avert deaths at roughly $1,200–2,200 each, mostly by steering treatment to severe cases.

These results do not show that FEWS NET saves lives. We cannot observe outcomes that do not depend on classifications made by FEWS NET or its partners, and the obvious natural experiments — the 2025 shutdown and earlier changes in FEWS NET coverage — turn out to be too weak to identify effects on welfare (Section 12). What the data do show is that FEWS NET produces information that other sources lack, that this information is borne out by later independent assessments, and that humanitarian money moves with it.

Related literature. Several studies score FEWS NET's forecasts against its own later maps. They find headline accuracy of 78–92 percent, falling in pastoral and conflict-affected areas and in strong El Niño years (Choularton and Krishnamurthy, 2019; Krishnamurthy et al., 2020; Backer and Billing, 2021; Bertetti et al., 2024). Because food security changes slowly, a forecast that nothing will change does nearly as well: Bertetti et al. (2024) find 78 percent accuracy for FEWS NET's near-term forecasts against 76 percent for persistence. Andrée et al. (2020) show that FEWS NET's outlooks miss most transitions into Crisis while rarely raising false alarms, and that machine-learning models trained on public data can trade some of that conservatism for more detection. Outside FEWS NET, Lentz et al. (2019) find that IPC zone classifications explain almost none of the variation in household food security measured by surveys in Malawi, and Lentz et al. (2025) argue that official IPC figures undercount acute hunger by about a fifth. Seyffer et al. (2026) compare FEWS NET and IPC projections in Somalia and find similar agreement with later assessments. We add three things. First, we score FEWS NET against independent assessments, not only its own later maps, and compare it directly with the official projections. Second, we use the Type I/Type II framework and FEWS NET's own aid flag to separate false alarms from crises held back by aid. Third, we measure FEWS NET's value relative to what donors would otherwise know, and link that marginal information to humanitarian funding. The last step connects to work

on what drives disaster and humanitarian aid, which finds that need explains only part of the allocation, alongside news coverage and donor politics (Eisensee and Strömberg, 2007; Drury et al., 2005; Fink and Redaelli, 2011).

The rest of the paper runs as follows. Section 2 describes FEWS NET and sets out why aid clouds the measurement of both errors. Section 3 describes the data. Sections 4 and 5 measure missed emergencies and false alarms. Section 6 asks what FEWS NET adds to what donors could otherwise know, and Section 7 whether money follows it. Section 8 asks what a phase means for malnutrition and death. Section 9 puts the pieces together into a rough benefit-cost calculation, Section 10 asks which parts of FEWS NET are worth paying for, and Section 11 whether paying for surveys would pay off. Section 12 explains what the data cannot tell us, and Section 13 concludes.

2 FEWS NET and the measurement problem

2.1 What FEWS NET produces

USAID created FEWS NET in 1985, after the Ethiopian and Sudanese famines of the mid-1980s. It monitors rainfall, harvests, markets, livestock, conflict and humanitarian assistance, and turns them into maps that classify each area of a country on the five-phase scale of the Integrated Food Security Phase Classification (IPC): Minimal (1), Stressed (2), Crisis (3), Emergency (4) and Famine (5) (IPC Global Partners, 2021). An area is placed in the highest phase that describes at least 20 percent of its population.

Three features of FEWS NET's products matter for this paper.

- **Current maps and forecasts.** Each round, FEWS NET publishes a map of the current situation and two forecasts: a near-term one for roughly the next four months and a medium-term one for the four months after that. Since 2016 these rounds have come three times a year, in February, June and October; before 2016, quarterly (FEWS NET, 2018).
- **Forecasts assume aid.** The forecasts build in humanitarian assistance that is planned and likely to be funded. A forecast of Emergency therefore means "Emergency even with the aid we expect," not "Emergency if nobody acts."
- **The aid flag.** FEWS NET marks an area with "!" when it judges that humanitarian assistance is keeping the area at least one phase better than it would otherwise be. The flag is FEWS NET's own estimate of what aid is preventing.

FEWS NET is not the only source of classifications. The IPC, a partnership of UN agencies, NGOs and governments, publishes area classifications and projections in many countries, and the Cadre Harmonisé does the same in West Africa. FEWS NET staff take part in many of these analyses. In much of FEWS NET's coverage, though, no official analysis exists for months at a time.

2.2 Two errors, and why aid hides them

Consider an area with underlying need N — the phase it would reach without aid — and observed phase P after any aid arrives. A forecaster issues warning W about N; donors respond with aid A, which lowers P relative to N. A Type II error is a crisis ($P \geq 4$, say) without a prior warning; a Type I error is a warning followed by no crisis.

Aid treats the two errors differently. Where a warning brings aid that works, $P < N$: a correct warning is recorded as a false alarm. Where no warning was issued, aid is less likely, and P is closer to N. So:

- observed false alarms overstate the true Type I error rate, by the number of crises prevented; and
- observed misses understate the true Type II error rate only if unwarned crises were nonetheless prevented by aid, which is less likely. Observed misses are close to a lower bound.

The same logic means that a system whose warnings work will look less accurate than one whose warnings are ignored. Any evaluation that scores forecasts only against outcomes penalizes successful early warning. This is the familiar problem of judging any response that goes where the problems are — hospitals have sicker patients, and countries under IMF programs have worse economies (Barro and Lee, 2005).

FEWS NET's aid flag offers a partial way out. If we take it at face value, an area mapped as Crisis with the flag had an underlying need of Emergency, and we can score warnings against need (P plus one if flagged) rather than outcome. We use this throughout, with two caveats: the same analysts produce the warning and the flag, and the flag records ongoing aid, not only aid that responded to the warning.

2.3 Two examples

Figures 1 and 2 show what FEWS NET's products look like in two crises. In each, the left panels show signals any donor could watch, and the right panels show FEWS NET's forecast and what it later mapped.

Somalia, 2016–17. The October–December 2016 rains failed: across Somalia's 199 FEWS NET areas, rainfall over the six months to January 2017 averaged −0.8 standard deviations below normal, with the deepest deficits in the north (panel A). Political violence was concentrated in the south (panel B). In February 2017 FEWS NET forecast Emergency for 26 areas by June, up from 16 at the time, including much of the north (panel C). By June, 29 areas were in Emergency — mostly in the south — and the north was mapped one phase lower, in Crisis, but flagged as held back by aid (panel D). In all, FEWS NET flagged 95 of the 199 areas (48 percent). This is the Type I ambiguity in miniature. The northern warnings did not come true as forecast, and FEWS NET's own map says that is because aid arrived.

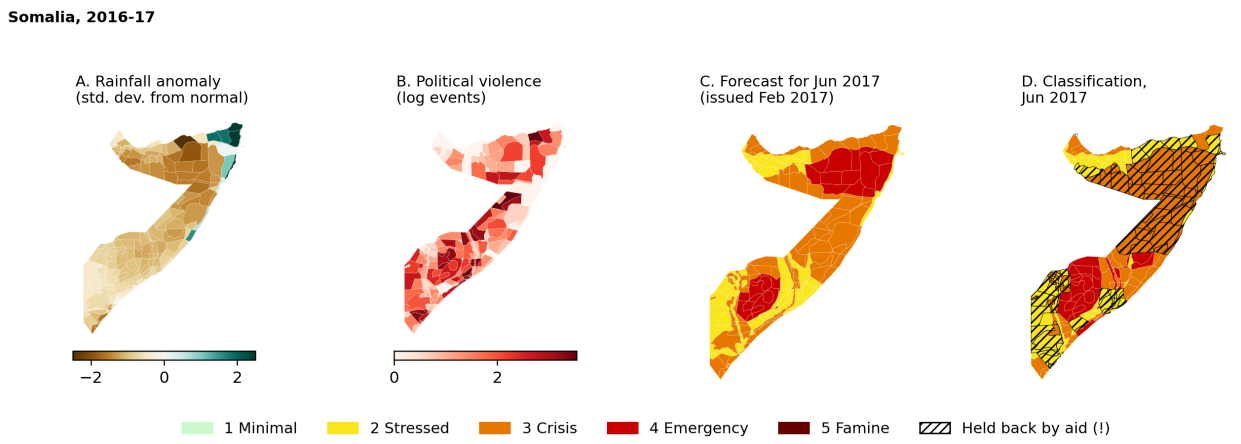

Figure 1: Somalia, 2016–17. FEWS NET areas. A: rainfall over the six months to January 2017, in standard deviations from the same months in the previous 20 years (CHIRPS). B: political violence events in the six months to January 2017 (ACLED, log of one plus events). C: FEWS NET's forecast, issued February 2017, for June 2017. D: FEWS NET's classification for June 2017; hatching marks areas FEWS NET flagged as held at least one phase better by humanitarian assistance.

Ethiopia, 2015–16. The El Niño drought hit the northern and central highlands: rainfall over the six months to September 2015 averaged −1.1 standard deviations below normal across Ethiopia's 678 FEWS NET areas, and much more in the worst-hit zones (panel A). Conflict was low and plays no role here. In October 2015, FEWS NET forecast Emergency for 26 areas by February 2016, up from 9 (panels B and C). By February, 24 areas were in Emergency, almost exactly where forecast, and FEWS NET flagged 103 areas (15 percent) as held back by aid. Many flags fell in areas mapped as Crisis in the north and as Stressed or Minimal in the south (panel D). Here the forecast came true, and FEWS NET credits aid with keeping the surrounding areas from following.

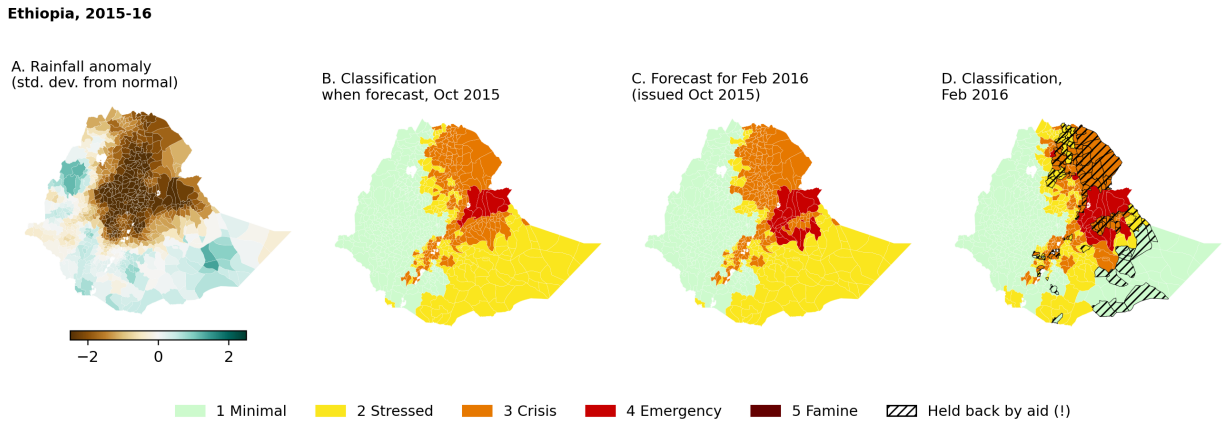

Figure 2: Ethiopia, 2015–16. FEWS NET areas. A: rainfall over the six months to September 2015, in standard deviations from the same months in the previous 20 years (CHIRPS). B: FEWS NET's classification in October 2015, when the forecast was issued. C: FEWS NET's forecast, issued October 2015, for February 2016. D: FEWS NET's classification for February 2016; hatching marks areas FEWS NET flagged as held at least one phase better by humanitarian assistance.

3 Data

Table 1 summarizes the data. All sources are public; Appendix A gives details and match rates.

FEWS NET. We use every current-situation map and forecast published through FEWS NET's data warehouse from January 2011 to December 2024 — 209,404 area-months in 16,684 areas and 37 countries. We stop at 2024 so that the 2025 shutdown does not distort the sample.

Independent classifications. The Cadre Harmonisé covers 19 West and Central African countries from 2014 and the IPC some 30 countries from 2017. For each area and analysis, we record whether the area is classified in Crisis or worse and the share of its population in Crisis or worse, for both the current situation and the projection. We overlay these areas on FEWS NET's to compare like with like. These classifications are independent of FEWS NET's own maps, but not of its staff, who join many IPC and Cadre Harmonisé analyses. They are the best independent benchmark available, not a perfect one.

Funding. The Financial Tracking Service records humanitarian commitments by recipient country and date. Over 2011–2024, FEWS NET countries received about 56 percent of all humanitarian funding; the United States provided about 52 percent of food and nutrition funding to these countries. We sum commitments to each country over the six months after each FEWS NET map round.

Raw signals. To represent what a donor could know without FEWS NET, we measure, for each FEWS NET area and round: rainfall over the previous 6 and 12 months relative to the same months in the preceding 20 years (CHIRPS); political violence events and deaths in the previous

Table 1: Data sources

Source	Content	Coverage used
FEWS NET Data Warehouse (FEWS NET, 2026)	Current-situation phases, near- and medium-term forecasts and aid flags for each FEWS NET area	209,404 area-months; 16,684 areas in 37 countries; 2011–2024
Cadre Harmonisé (Cadre Harmonisé, 2026)	Area classifications and projections, West and Central Africa	2014–2026; district or region level
IPC (IPC Global Partners, 2026)	Area classifications and projections outside West Africa	2017–2026
Global Report on Food Crises (FSIN and Global Network Against Food Crises, 2025)	People in Crisis or worse, by country and year	2016–2024; 70 countries
OCHA Financial Tracking Service (UN OCHA, 2026)	Humanitarian funding commitments by recipient, sector and date	2011–2024
CHIRPS (Funk et al., 2015)	Monthly rainfall, 0.05° grid (aggregated to 0.2°)	1981–2026
ACLED (Raleigh et al., 2010; ACLED, 2026)	Political violence events and deaths by district and month	19 countries with sub-national data
WFP market prices (World Food Programme, 2026)	Retail prices of cereals and tubers by market	Nearest market within 150 km

Notes: FEWS NET areas are livelihood zones or administrative units, depending on the country. IPC and Cadre Harmonisé areas are matched to FEWS NET areas by spatial overlay.

6 months and their change on a year earlier (ACLED), apportioned from districts by area; and 3- and 12-month changes in retail cereal prices at the nearest WFP market. Rainfall covers 99 percent of area-rounds, conflict 48 percent and prices 28 percent; models treat missing values as missing.

Coverage. Figure 3 shows why FEWS NET matters. Over 2016–2024, the countries FEWS NET monitored accounted for 69 percent of the world's person-years in Crisis or worse, and 82 percent of those in Emergency or worse, across the 70 countries in the Global Report on Food Crises. The largest crises outside its coverage were Syria, Pakistan, Bangladesh and Myanmar.

4 Type II errors: missed emergencies

We define a new emergency as an area mapped in Emergency or worse whose previous map, no more than six months earlier, placed it below Emergency. Between 2011 and 2024 there were 1,562 such cases. For each, we look back at every forecast FEWS NET issued for that area and month in the preceding one to eight months.

Figure 4 shows the result. Panel A plots, by how far ahead the forecast was made, the share of new emergencies that FEWS NET forecast to be in Emergency (dark line) and in Crisis or worse (light line). Almost all new emergencies were foreseen as crises: at four months, 95 percent had been forecast to be in at least Crisis. Few were foreseen as emergencies: 22 percent at eight months, 42 percent at four months and 63 percent one month ahead. Panel B gives the most severe forecast

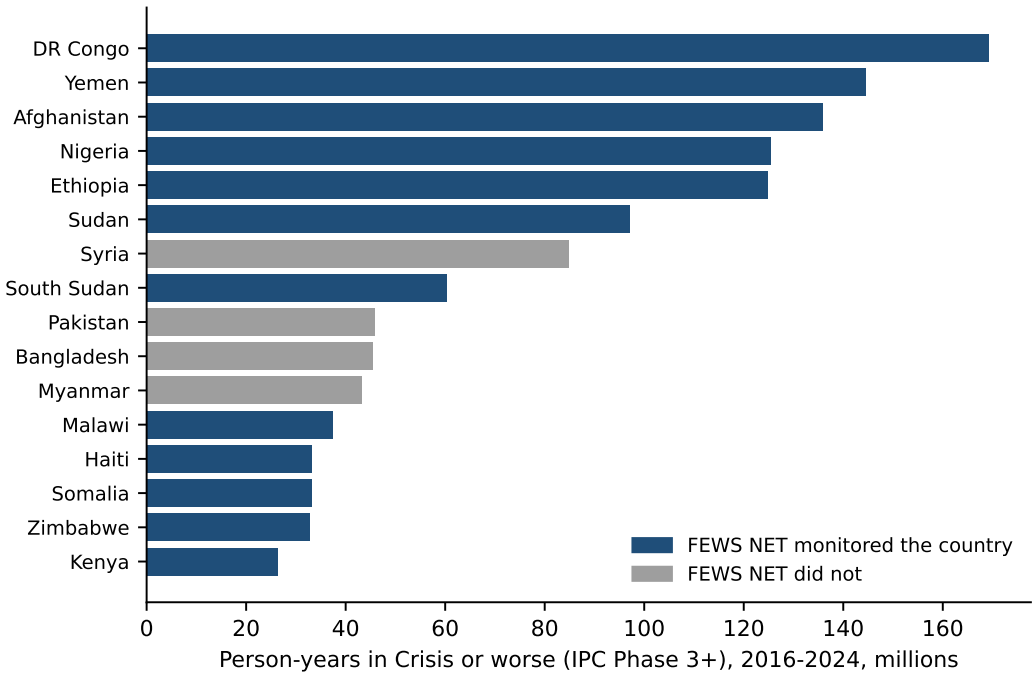

Figure 3: Where the world's food crises are. Person-years in Crisis or worse (IPC Phase 3 and above), 2016–2024, for the 16 countries with the most, by whether FEWS NET monitored the country. Source: Global Report on Food Crises country-year database.

made four to eight months ahead — the window that matters for mobilizing aid. 47 percent were forecast as Emergency, 42 percent as Crisis, and 11 percent as Stressed or better.

These numbers say that FEWS NET's Type II errors are mostly errors of degree, not of kind. Only 4 percent of new emergencies came with no warning of at least Crisis. The warnings also discriminate: four months ahead, FEWS NET forecast Emergency for 42 percent of areas that went on to tip into Emergency, but for only 1.3 percent (on average across horizons) of comparable areas that did not. What FEWS NET does badly is forecast escalation from Crisis to Emergency — the step at which, in the IPC's definitions, very high acute malnutrition and excess mortality are expected.

A wider lens tells the same story. Food security changes slowly: in 79 percent of area-rounds, an area's next map shows the same phase as its current one. FEWS NET's medium-term forecast matches the next map 84 percent of the time, against 79 percent for a forecast that nothing changes. Among the 21 percent of area-rounds in which the phase did change, the forecast was right 55 percent of the time. These numbers score FEWS NET against itself and so flatter it, but the conclusion is consistent with earlier evaluations: most of FEWS NET's headline accuracy comes from stable areas, and its skill on change is real but partial.

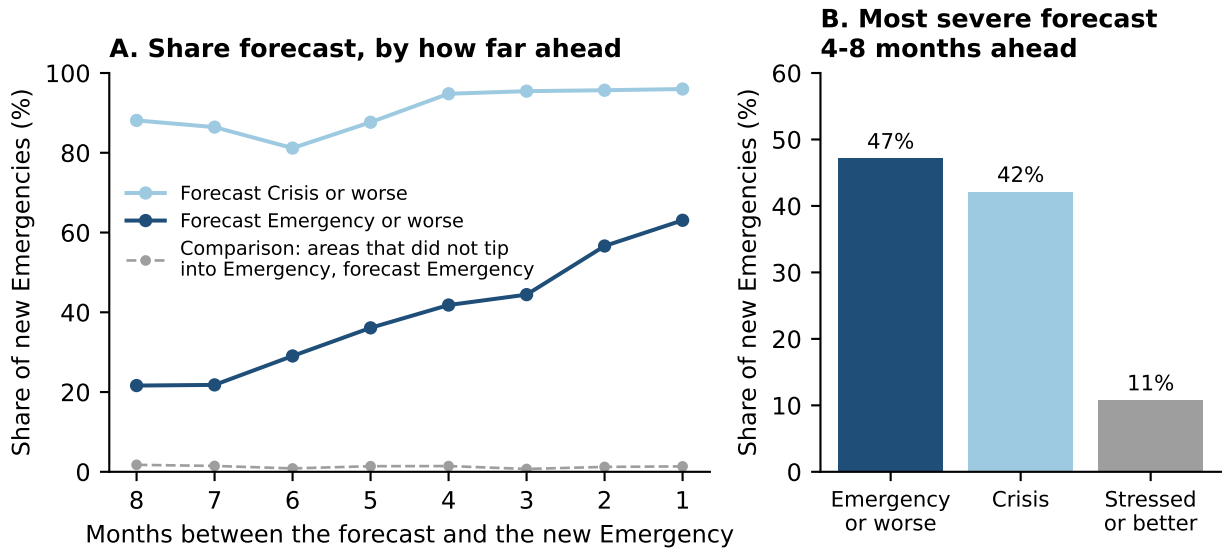

Figure 4: Were new emergencies foreseen? 1,562 FEWS NET areas that entered Emergency or worse (IPC Phase 4+) in 2011–2024, after a previous map below Emergency. Panel A: share of these areas that FEWS NET had forecast, k months earlier, to be in Emergency or worse (dark) or Crisis or worse (light), for the outcome month or the three months before it. The grey dashed line shows the share of areas that did *not* tip into Emergency that were forecast to be in Emergency. Panel B: the most severe forecast issued four to eight months before the new emergency.

5 Type I errors: false alarms

We define an emergency warning as a forecast, issued four to eight months ahead, that an area would be in Emergency or worse in a month for which FEWS NET later published a current-situation map. There were 4,084 such area-month warnings between 2011 and 2024.

Figure 5 shows what happened to them. In 46 percent of cases the area was in Emergency or worse, as forecast. In 54 percent it was not. Almost all of those ended one phase lower, in Crisis; only 3 percent ended in Stressed or better.

FEWS NET's aid flag lets us ask how many of these apparent false alarms FEWS NET itself attributes to aid. Of the warned areas that ended in Crisis, 60 percent carried the flag, against 12 percent of Crisis areas that had not been warned about. Taken at face value, the flag reclassifies 30 percent of all emergency warnings as crises held back by aid, leaving 20 percent ending in Crisis without the flag and 3 percent ending lower. On this reading, about a quarter of FEWS NET's emergency warnings were genuine false alarms.

The pattern differs sharply across countries (Figure 5, panel B). In Sudan, Nigeria and Ethiopia, two-thirds or more of emergency warnings came true. In Somalia and Kenya, fewer than a quarter did, and FEWS NET credited aid with holding back about half or more of the rest. In Sudan, where warnings failed, FEWS NET almost never credited aid.

Two checks suggest caution before crediting aid with the rest.

First, 48 percent of the warned areas that ended in flagged Crisis had carried the flag on the

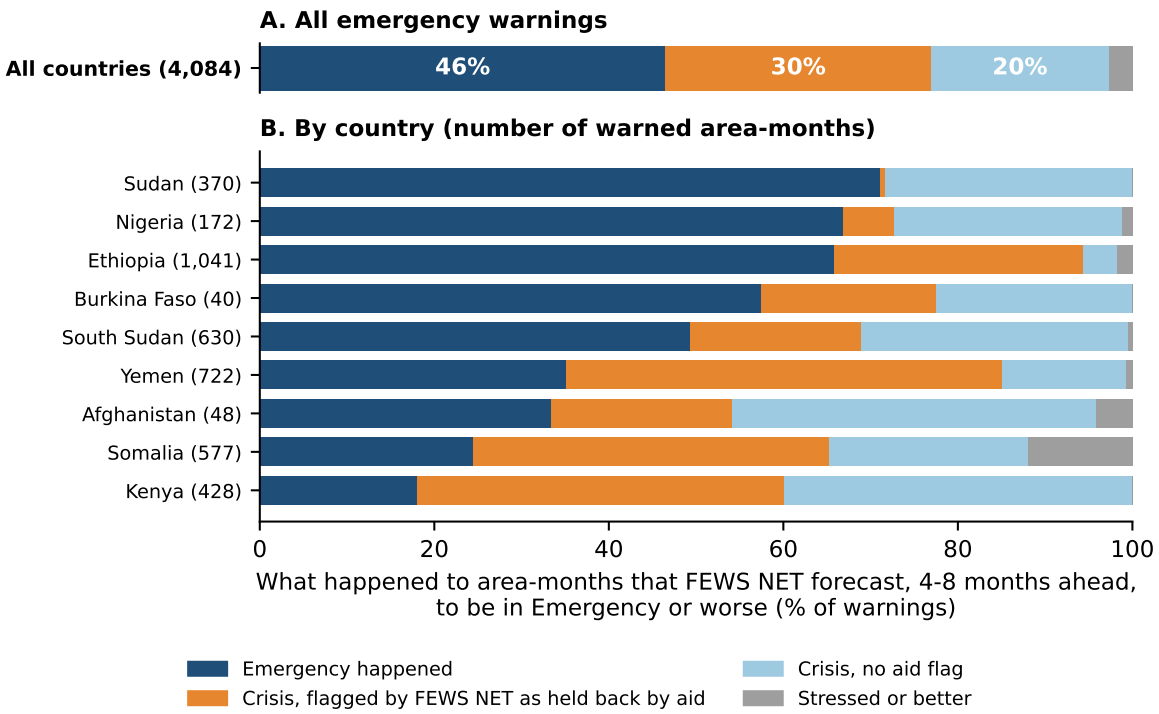

Figure 5: What happened to emergency warnings. Area-months that FEWS NET forecast, four to eight months ahead, to be in Emergency or worse (IPC Phase 4+), 2011–2024, by the phase FEWS NET later mapped. Panel A: all countries. Panel B: countries with at least 40 warned area-months. "Held back by aid" means FEWS NET's map carried its "!" flag: humanitarian assistance was keeping the area at least one phase better than it would otherwise be.

map before the warning was issued. In those areas, the flag describes aid that was already flowing, not aid mobilized by the warning. The forecast should already have accounted for it, since FEWS NET's forecasts assume planned assistance. One reading is that FEWS NET forecast Emergency on the expectation that existing aid would fall away, and it did not; another is that the flag rationalizes a forecast that was too pessimistic. The data cannot distinguish them.

Second, if aid were preventing warned emergencies, warnings should come true less often when money then arrived. We test this in Appendix B using FEWS NET's "distinctive" warnings — the part of each forecast that rainfall, conflict, prices and the previous maps do not predict (Section 6). We compare countries whose humanitarian funding over the following six months rose more than their usual level and recent trend would predict with countries whose funding rose less. The share of distinctive warnings borne out is 0.50 where funding rose less than usual and 0.49 where it rose more. Scoring against need (the mapped phase plus one if flagged) gives 0.51 and 0.49. We find no sign that funding surprises mask accuracy. Funding is only observed by country, so this test is coarse; it does not rule out well-targeted aid within countries.

Defining emergencies by need gives a similar picture. If we count an area as reaching Emergency when its mapped phase plus the aid flag reaches 4, there were 2,338 such cases, and 55 percent were held back by aid on FEWS NET's own account. But 78 percent of those held back were

areas already in Crisis whose phase did not change; the flag simply switched on. And among these need-defined emergencies, early warning did not raise the share held back by aid (-6 percentage points, standard error 5). FEWS NET's forecasts already assume the aid that is coming, so they are not designed to answer this question.

6 Does FEWS NET know something others don't?

Accuracy against FEWS NET's own later maps says little about value. What matters for a funder is what would be lost without FEWS NET: its information relative to what donors could otherwise see, scored against outcomes it did not produce. We approach this in two ways.

6.1 Against a world without FEWS NET

We define two benchmarks for what donors would know without FEWS NET. The first uses only raw signals: local rainfall, conflict and food prices before the forecast, plus country and season. The second adds the latest official IPC or Cadre Harmonisé analysis of the area, if one was made in the previous eight months. The second benchmark is generous to the world without FEWS NET, because FEWS NET staff contribute to many official analyses. It is also usually unavailable: only 25 percent of FEWS NET's area-rounds had a recent official analysis.

For each benchmark, we use gradient-boosted trees to predict two things out of sample (each year predicted from models fitted on the other years): FEWS NET's own current map and forecast, and the outcome in the next official analysis. "FEWS NET's contribution" is the part of its map or forecast that the benchmark does not predict. We then score everything against the next independent IPC or Cadre Harmonisé analysis of the area. We focus on areas that were not in Crisis at the latest official analysis, because predicting that a crisis continues is easy. This leaves 12,776 area-rounds in which 1,009 areas tipped into Crisis.

Figure 6 gives the main result as the area under the ROC curve (AUC): the probability that a randomly chosen area that tipped into Crisis is ranked above one that did not. Adding FEWS NET's map and forecast to the raw signals raises the AUC from 0.79 to 0.85, closing more than a quarter of the gap to perfect ranking. Adding them to the more generous benchmark raises it from 0.84 to 0.86.

The second gain is small, and it is worth being clear about why it does not undercut the rest of the paper. First, it is measured where FEWS NET's alternatives are strongest. The benchmark includes the latest official analysis, which exists for only 25 percent of FEWS NET's area-rounds, and every observation in this test is, by construction, an area the IPC or Cadre Harmonisé covers. Second, those official analyses are not independent of FEWS NET: its analysts take part in them and its data feed them, so the benchmark already contains much of what FEWS NET knows. Third, the AUC is close to its ceiling; the move from 0.84 to 0.86 closes about an eighth of the remaining gap, and the regressions below find the gain precisely estimated. The fair reading is that where a recent official analysis exists, FEWS NET adds modestly to it. FEWS NET's distinctive

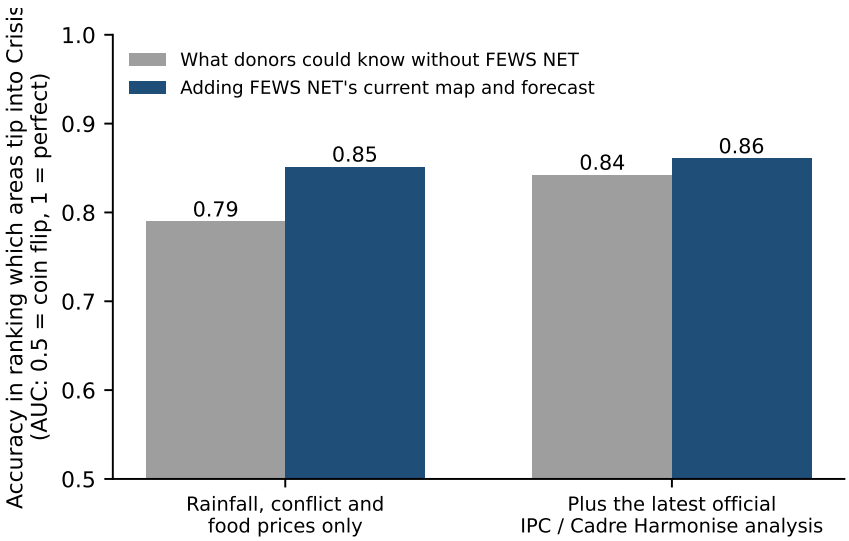

Figure 6: FEWS NET's information beyond what donors could otherwise know. Accuracy in ranking which areas tip into Crisis or worse at the next official IPC or Cadre Harmonisé analysis, among 12,776 area-rounds not in Crisis at the latest official analysis (1,009 tipped into Crisis), 2011–2024. Grey: out-of-sample predictions from rainfall, conflict, prices, country and season (left), plus the latest official analysis (right). Blue: the same models with FEWS NET's current map and forecast added. AUC is the probability that an area that tipped into Crisis is ranked above one that did not.

value lies mainly where none exists — three-quarters of its coverage — and there we cannot score it against an independent outcome. Section 7 shows that funding behaves accordingly.

Table 2 gives the regression version. The outcome is whether the area is in Crisis or worse at the next official analysis. We regress it on the benchmark's own prediction of that outcome and on FEWS NET's contribution, with country-by-round fixed effects, so the comparison is between areas in the same country at the same time:

$$y_{a,t+1} = \alpha\, \hat{y}_{at} + \beta\, c_{at} + \mu_{c(a),t} + \varepsilon_{at},$$

where $y_{a,t+1}$ is an indicator for Crisis or worse in area a at the next official analysis, $\hat{y}_{at}$ is the benchmark's prediction of it, c_{at} is FEWS NET's contribution (its map or forecast minus the benchmark's prediction of that map or forecast), and $\mu_{c(a),t}$ is a country-by-round fixed effect. The coefficient β measures how much of FEWS NET's distinctive signal is borne out by an independent assessment. Over the raw-data benchmark, it is 0.13 for the current map and 0.13 for the forecast when both enter (column 3); over the benchmark with official analyses, 0.12 and 0.08 (column 6). All are precisely estimated.

The coefficients are well below one. Only part of FEWS NET's distinctive signal shows up in the next official assessment. Some of the gap is noise in FEWS NET's judgments, some is noise in the official assessments, and some, if aid works, is masking. But the signal is clearly there, and it survives controlling for the official analyses that do exist.

Table 2: Is FEWS NET's distinctive information borne out by independent assessments?

	Without FEWS NET: rainfall, conflict and prices			Without FEWS NET: rainfall, conflict, prices and latest official analysis		
	(1)	(2)	(3)	(4)	(5)	(6)
FEWS NET current map, beyond the baseline	0.201***		0.127***	0.165***		0.121***
	(0.015)		(0.023)	(0.013)		(0.020)
FEWS NET forecast, beyond the baseline		0.195***	0.131***		0.142***	0.082***
		(0.011)	(0.019)		(0.016)	(0.023)
Baseline's own prediction (coefficient)	0.42	0.42	0.44	0.68	0.68	0.68

Countries	21	21	21	21	21	21
AUC: baseline → adding FEWS NET		0.79 → 0.85			0.84 → 0.86	

Notes: Linear probability models. Outcome: area classified in Crisis or worse (IPC Phase 3+) at the next official IPC or Cadre Harmonisé analysis. Sample: official areas not in Crisis at the latest official analysis, 2011–2024. FEWS NET's map and forecast are overlaid onto official areas (share of the area in Crisis or worse). "Beyond the baseline" is FEWS NET's map or forecast minus its out-of-sample prediction from the baseline (gradient-boosted trees, fitted on other years). All columns control for the baseline's own out-of-sample prediction of the outcome and include country-by-round fixed effects. Standard errors clustered by country in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. The last row gives the AUC for ranking areas that tip into Crisis, using the baseline alone and adding FEWS NET's map and forecast.

6.2 Head to head with the official projections

The IPC and Cadre Harmonisé also publish forecasts. Where both exist, we compare FEWS NET's forecast with the official projection for the same area and period, both scored against the next official current analysis. We match each official projection to FEWS NET's forecast from its latest round at or up to four months before the official analysis. This gives 6,683 area-projections in 14 countries; 4,128 of them were not in Crisis at the latest official analysis, and 227 of those tipped into Crisis. In the Cadre Harmonisé, projections target the June–August lean season, which is rarely assessed as a current period; we score them against the next current analysis (September–December). Both forecasters face the same mismatch.

Figure 7 plots both forecasts in Type I/Type II space. The vertical axis is the share of new crises that were not warned about (misses); the horizontal axis is the share of areas that stayed out of Crisis but were warned about (false alarms). The official projection classifies the area in Crisis for 42 percent of new crises, at a false alarm rate of 12 percent. FEWS NET forecasts Crisis for most of the area in 37 percent of new crises, at a false alarm rate of 7 percent. FEWS NET is more conservative: it misses slightly more but cries wolf less. The two are complements. Warning when either one warns catches 55 percent of new crises at a false alarm rate of 15 percent. In 12 percent of new crises, FEWS NET warned and the official projection did not.

Table 3 regresses the next official classification on both forecasts. FEWS NET's forecast predicts the outcome over and above the official projection. With both forecasts and the latest official analysis (column 4), the coefficient on FEWS NET's forecast is 0.18 and on the official projection 0.06. For areas not yet in Crisis (Panel B, column 3), they are 0.15 and 0.05. With only 12 to 14 countries, cluster-robust standard errors can overstate precision; wild cluster bootstrap p-values for FEWS NET's coefficient are 0.003 and 0.006.

These comparisons are partly circular: FEWS NET analysts join many official analyses, and

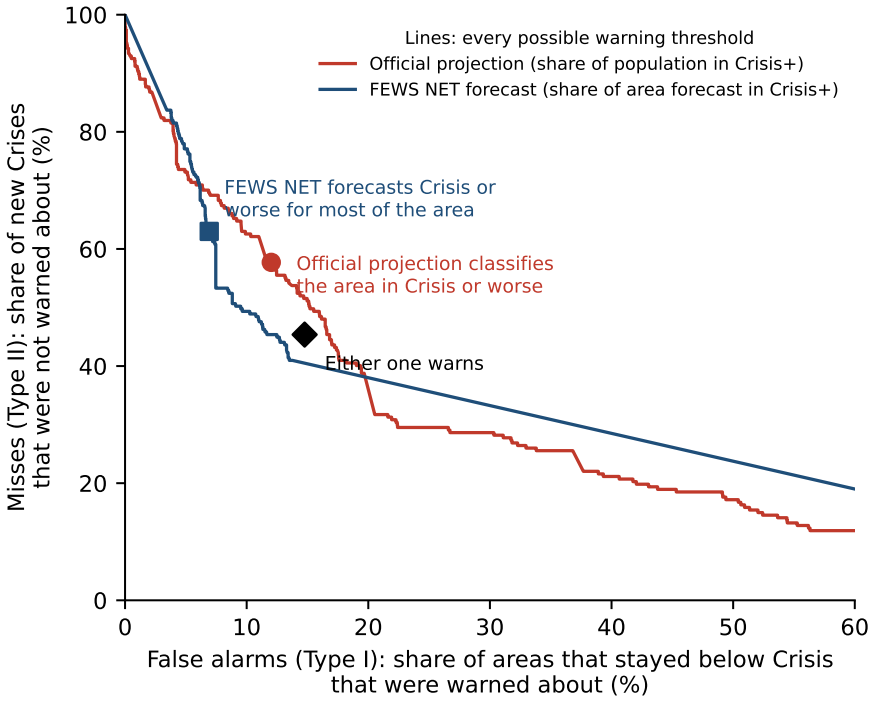

Figure 7: FEWS NET and the official projections in Type I/Type II space. 4,128 official IPC and Cadre Harmonisé areas not in Crisis at the latest official analysis, in 12 countries, 2014–2025; 227 tipped into Crisis at the next official analysis. Points: misses (new crises not warned about) and false alarms (areas warned about that stayed out of Crisis) for the official projection classifying the area in Crisis or worse, FEWS NET forecasting Crisis or worse for most of the area, and either one warning. Lines trace every warning threshold for the official projection (share of the population projected in Crisis or worse) and for FEWS NET (share of the area forecast in Crisis or worse). Lower and further left is better.

both teams read each other's work. That makes it more notable, not less, that FEWS NET's forecast keeps predictive power after controlling for the official projection.

Table 3: FEWS NET's forecasts and the official projections, scored against the next official analysis

	(1)	(2)	(3)	(4)	(5)

Countries	12	12	12	12	12

Notes: Linear probability models. Outcome: area classified in Crisis or worse (IPC Phase 3+) at the next official IPC or Cadre Harmonisé current analysis after the projection. Official projection: Cadre Harmonisé March projections for June–August, and IPC first projections. FEWS NET forecast: share of the official area that FEWS NET's latest forecast (issued up to four months before the official analysis) placed in Crisis or worse for the projection period. All columns include country-by-analysis-round fixed effects. In Panel B, the latest official analysis is constant by construction, so column (4) repeats column (3). Standard errors clustered by country in parentheses; with 12–14 clusters, see wild bootstrap p-values in the text. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

7 Does money follow the warnings?

Information has value only if someone acts on it. We cannot observe aid at the level of FEWS NET's areas, so we ask whether humanitarian funding to a country moves with FEWS NET's classifications of that country. For each country and FEWS NET round, we regress the log of humanitarian funding committed over the next six months on the share of the country's FEWS NET areas in Crisis or worse on the current map, and on the share forecast to be in Crisis or worse four to eight months ahead.

Across countries, funding follows FEWS NET's maps closely. Without controls, and holding the current map fixed, a 10 percentage point rise in the share of a country's areas forecast to be in Emergency goes with 76 percent more humanitarian funding (95 percent interval 44 to 115). Most of this reflects persistent differences between countries: large, chronic crises get both bad maps and more money. Figure 8A shows what survives as controls are added for global funding swings, the country's funding in the previous six months, and the country's usual aid level. With all controls, the current map no longer predicts funding (−2 percent for food and nutrition funding per 10 percentage points of areas in Crisis), but the forecast does (25 percent; interval 5 to 48). Within a country, money moves when FEWS NET expects things to get worse, not when it reports that they are bad. The Emergency shares are too rarely nonzero within countries to estimate this precisely (Appendix Table A1).

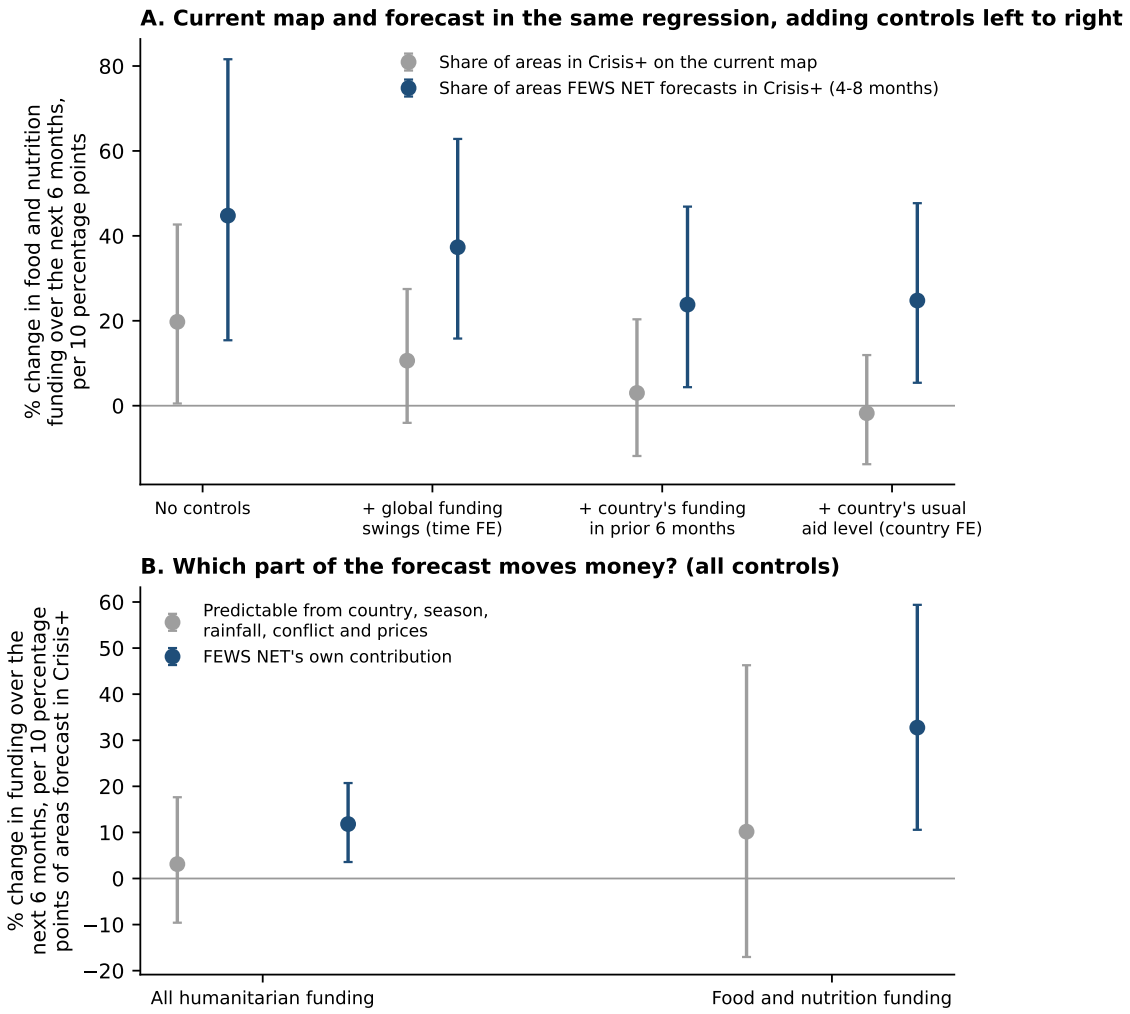

Figure 8: Does humanitarian funding follow FEWS NET? Country × FEWS NET round, 2011–2024. Outcome: humanitarian funding committed to the country over the next six months (OCHA Financial Tracking Service, log), expressed as the percent change per 10 percentage points more of the country's FEWS NET areas in Crisis or worse. Panel A: the share in Crisis or worse on the current map and the share forecast in Crisis or worse four to eight months ahead, in the same regression, adding controls from left to right. Panel B: the forecast split into the part predictable from rainfall, conflict, prices, country and season, and FEWS NET's own contribution; with time and country fixed effects and funding in the previous six months. 95 percent intervals clustered by country.

Does funding respond to FEWS NET's own information, or to the rainfall failures and conflict that donors could see directly? Panel B splits the forecast into the part predictable from the country, the season and raw signals, and FEWS NET's contribution. The predictable part is mostly country and season: those alone account for 61 percent of its variation, and within a country and season, rainfall, conflict and prices explain only 5 percent of the variation in FEWS NET's forecasts. Across country-rounds, the predictable part varies little within countries (standard deviation 0.10, against 0.22 overall), while FEWS NET's contribution varies almost entirely within them (0.15 of 0.15). Only the contribution predicts funding: 12 percent more humanitarian funding (interval

4 to 21) and 33 percent more food and nutrition funding (11 to 59) per 10 percentage points of areas FEWS NET forecasts in Crisis beyond what that information predicts. The predictable part has no detectable effect (3 and 10 percent, with wide intervals). Results are similar against the benchmark that includes official analyses (Table A1). Funding follows FEWS NET's distinctive information more strongly where official analyses are scarce. In country-rounds where fewer than half of FEWS NET's areas had a recent official analysis (32 percent of country-rounds have more), a 10 percentage point rise in its distinctive forecast comes with 13 percent more humanitarian funding and 39 percent more food funding. Where official analyses are common, the figures are 8 and 16 percent. The difference is imprecise (standard errors 0.59 and 1.31 log points per unit), but it matches the pattern in Section 6.

These are associations, not causal effects. Donors and FEWS NET may respond to the same news that our raw signals miss — a displacement wave, a government request, a news story. But the pattern is the one we would expect if FEWS NET's forecasts inform allocation: funding responds to the forward-looking, distinctive part of FEWS NET's analysis, and not to what anyone could infer from a country's usual situation and public data.

Within countries. Funding data are recorded by country, so we cannot see whether aid goes where FEWS NET points within a country. A partial check uses the small share of aid that can be located by district: the UN's country-based pooled funds, about 3–5 percent of humanitarian funding, together with records of which organizations work where and how many people they reached, for Somalia and Sudan (Appendix G). In Somalia the located money follows FEWS NET's forecasts, but only the part that public information predicts, and FEWS NET's next forecast predicts it about as well, so money and forecasts track the same conditions. In Sudan it does not follow the forecasts. FEWS NET's aid flags track where aid organizations work only loosely. Because located aid is such a small and atypical slice of the total, we treat these results as suggestive at most.

8 What does a phase mean for lives?

Everything so far concerns FEWS NET's phases: whether it forecasts them well, and whether money follows them. To turn phases into lives, the next section needs to know how many more children are malnourished, and how many more people die, in an area that is one phase worse. The usual answer is the IPC's reference table, which ties each phase to a band of crude death rates (below 0.5 deaths per 10,000 people per day in Phases 1 and 2, 0.5–1 in Crisis, 1–2 in Emergency and above 2 in Famine) and of acute malnutrition among children under five (below 5, 5–10, 10–15, 15–30 and above 30 percent) (IPC Global Partners, 2021, 2019). This section asks whether measured outcomes follow those bands. We know of no study that systematically compares survey-measured child wasting or mortality with the acute food insecurity phase of the same area across countries, or that scores IPC, Cadre Harmonisé or FEWS NET classifications

against anthropometry or mortality measured later. The closest evidence is fragmentary. The IPC's own guidance notes that acute food insecurity and acute malnutrition phases often diverge — in 2020 only 3 of 9 districts of Karamoja in Uganda had the same phase on both scales — but reports no systematic statistics (IPC Global Partnership, 2024). A Somalia forecasting study includes the district share of the population in Phase 3 or worse among many candidate predictors of acute malnutrition, and finds it significant, without reporting its size (Reusken et al., 2025). Mortality studies use IPC phases only to define baseline periods or as a visual cross-check (Checchi and Robinson, 2013; Warsame et al., 2023; Ratnayake et al., 2025), and a recent review concludes that the link between food insecurity and mortality in humanitarian settings cannot be answered with current evidence (Annan et al., 2023).

8.1 Why the bands may not hold

The bands were not derived from food insecurity data. They descend from 1980s and 1990s benchmarks for refugee camps: a doubling of a baseline crude death rate of about 0.44, and camp-based relations between wasting and mortality (Young and Jaspars, 2009). When the IPC created a separate scale for acute malnutrition in 2016, it noted that food insecurity and acute malnutrition do not always match, in either direction (IPC Nutrition Working Group, 2016). Acute malnutrition depends on disease, water, sanitation and care as well as food. A meta-analysis of household studies finds that food insecurity predicts stunting and underweight but not wasting (Moradi et al., 2019), and studies in Chad, Darfur, South Sudan and Niger find wasting hotspots that do not coincide with food-insecurity hotspots (Young and Marshak, 2017; Luc et al., 2023). In Somalia, models that forecast acute malnutrition lean mainly on its own past values (Checchi et al., 2022; Reusken et al., 2025), and a FEWS NET causal analysis in Niger found household food insecurity not independently associated with wasting (McDonald, 2017).

8.2 Method

We use three kinds of evidence. First, survey measurements matched to FEWS NET's phase for the same area and time. For a survey of area a in season t, with measured outcome y_{at} (acute malnutrition, or a crude or under-five death rate) and FEWS NET phase P_{at} (its forecast for the survey month, or its map), we estimate

$$y_{at} = \beta P_{at} + \mu_a + \lambda_t + \varepsilon_{at}.$$

Without the area effects μ_a, β compares different areas: are areas in worse phases worse off? With them, it compares the same area over time: when an area is one phase worse than usual, how much worse are its outcomes? The second is what the benefit-cost calculation needs, since it asks what happens when aid holds a given area one phase better. The season effects λ_t remove shocks common to the country in a season. We also score FEWS NET's forecast as a predictor of y_{at} out of sample, leaving out one season at a time, against the simplest alternative: the area's own

measurement in the previous round.

Which surveys are used matters. Surveys sent where trouble is suspected will overstate the link between phase and outcome, because they are fielded where both are bad (Section 10). So we rely mainly on scheduled surveys, fielded on a fixed calendar whatever the conditions, and treat ad hoc surveys as an upper bound. Second, we compare the IPC's two scales, for acute food insecurity and for acute malnutrition, where both classify the same area. Third, we compare the excess deaths estimated in documented crises with the number of people in Crisis or worse.

8.3 Somalia's scheduled surveys

Somalia's Food Security and Nutrition Analysis Unit (FSNAU), managed by FAO, surveys the country's rural livelihood zones, towns and displaced settlements twice a year, after the Gu and Deyr rains, on a fixed calendar. We assembled all 1,229 survey results it published from late 2010 to 2026, from its results portal and its technical reports. We kept the rural SMART surveys run by FSNAU itself and matched each surveyed zone to FEWS NET's mapping units by livelihood zone and region. That leaves 329 zone-seasons in 29 zones over 28 seasons with FEWS NET's forecast, its current map and the zone's result from the previous round. Mean acute malnutrition was 13 percent, and 33 percent of zone-seasons were at or above the critical level of 15 percent. Two caveats apply. Insecure zones of south-central Somalia, notably Juba, South Gedo and parts of Bakool and Hiran, were often skipped or assessed only by arm-circumference screening, so the worst-hit areas are under-represented. And FSNAU's analysts work alongside FEWS NET's, though the survey measurements are independent of the classifications.

Across zones, FEWS NET's phases do not track measured malnutrition (Figure 10, blue points). Mean acute malnutrition was 13 percent in zones FEWS NET forecast to be Stressed or better, 13 percent in zones forecast to be in Crisis and 15 percent in zones forecast to be in Emergency or worse. The correlation between FEWS NET's forecast, issued a median of 3 months ahead, and the measured rate is 0.10. The correlation with FEWS NET's map published just after the survey, which could draw on its results, is 0.09. The zone's own result six months earlier correlates 0.66 with this round's (Figure 11). Out of sample, the previous survey explains 0.42 of the variance in acute malnutrition, and FEWS NET's forecast explains none (R^2 of -0.10); adding the forecast to the previous survey does not help (0.41). For predicting whether a zone reaches the critical level, the AUC is 0.75 with the previous survey and 0.47 with FEWS NET's forecast. The same holds for under-five death rates: out-of-sample R^2 of 0.20 for the previous survey and -0.07 for the forecast.

Within zones there is a gradient, but a small one (Figure 9). When FEWS NET forecast a zone to be one phase worse than usual, its acute malnutrition was 0.8 points higher (standard error 0.3), or 0.5 points (0.3) with season effects. Its crude death rate was 0.12 deaths per 10,000 per day higher (0.03), or 0.08 (0.04) with season effects, and its under-five death rate 0.25 (0.07) or 0.14 (0.08) higher. Using FEWS NET's map after the survey instead of its forecast gives similar estimates. At their midpoints, the IPC bands imply 5 points of acute malnutrition and 0.45 deaths per 10,000 per day for a step from Stressed to Crisis, and 10 points and 0.75 deaths for a step from

Crisis to Emergency.

The estimates may be biased down: the phase of a survey zone averages several FEWS NET units, which adds noise, and the worst-hit zones are under-surveyed. They are consistent with Reusken et al. (2025), who find that the official share of a district's population in Phase 3 or worse helps predict its acute malnutrition: a link exists, but it is far weaker than the bands imply.

8.4 Other countries

We repeated the comparison with two open sources. The SMART+ dashboard run by Action Against Hunger and UNICEF holds 246 survey results from 2022 to 2026, mostly from Nigeria, Ethiopia and Mozambique, 167 of which fall in FEWS NET's maps; 90 come from Nigeria's recurring UNICEF survey rounds and the rest are ad hoc. FEWS NET's data warehouse holds 389 results from national survey rounds in Burkina Faso and Mauritania, 2003–2018.[1] The gradient is steeper than in Somalia but still well below the bands (Figure 10, orange and green points). In SMART+, mean acute malnutrition was 9, 10, 11 and 18 percent in areas FEWS NET mapped in Phases 1, 2, 3 and 4 or worse (correlation 0.32); the jump at Phase 4 comes mostly from a dozen ad hoc surveys in Ethiopia. With country-by-year effects, one phase goes with 1.8 points of acute malnutrition (standard error 0.5). Nigeria's recurring rounds give 2.7 points (0.8) per Cadre Harmonisé phase, and the Burkina Faso and Mauritania rounds 3.3 (1.1) per FEWS NET phase. Crude death rates do not rise with FEWS NET's phase at all (Figure 12): 0.32, 0.45, 0.40 and 0.31 deaths per 10,000 per day across the four groups (slope 0.00, standard error 0.04). Against the official IPC or Cadre Harmonisé phase, they rise by 0.17 per phase (0.05).

The IPC's own two scales tell the same story (Figure 13). Where an area has both an acute food insecurity phase and an acute malnutrition phase for the same period, the two correlate 0.13 and agree exactly in 42 percent of 600 areas in the Democratic Republic of Congo, Nigeria and South Sudan. Classifying acute malnutrition from published prevalence in 8 countries gives a correlation of 0.20 across 902 areas. Pooling both, the two scales put an area in the same phase only 35 percent of the time across 1,427 areas, and areas the food insecurity scale calls Crisis are spread almost evenly across all four malnutrition phases.

8.5 Excess deaths in documented crises

The most direct evidence on mortality comes from crises whose death tolls have been estimated. Dividing estimated excess deaths by the number of people in Crisis or worse gives an excess death rate per person in Phase 3 or worse of roughly 0.15–0.2 per 10,000 per day in Somalia's 2017–18 and 2022 droughts (Warsame et al., 2023; London School of Hygiene & Tropical Medicine et al., 2023; Ouchtar et al., 2026), about 0.9 in northeast Nigeria in 2016–19 (Checchi et al., 2023), and 1.1–1.9 in the 2010–12 Somalia famine, which met a late response (Checchi and Robinson, 2013). Figure 14 sets these against the IPC's Crisis band. Measured crude death rates in areas reviewed

[1] The warehouse lists several thousand Ethiopian survey results as public, but does not return their values.

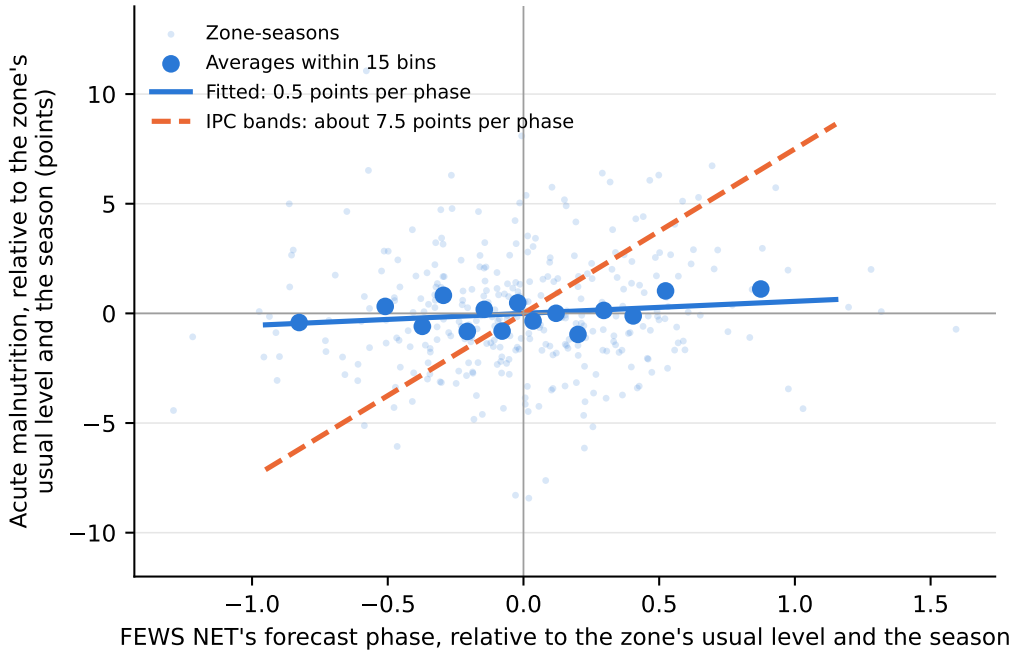

Figure 9: Within zones: when FEWS NET forecasts a Somali zone to be worse than usual, is its measured malnutrition worse than usual? Both variables are measured relative to the zone's own average and the season's average across zones (zone and season effects removed). Light points: 329 zone-seasons; dark points: averages within 15 equal-sized bins of the forecast. Solid line: fitted slope. Dashed line: the slope implied by the IPC reference bands, roughly the average of the 5- and 10-point steps between band midpoints.

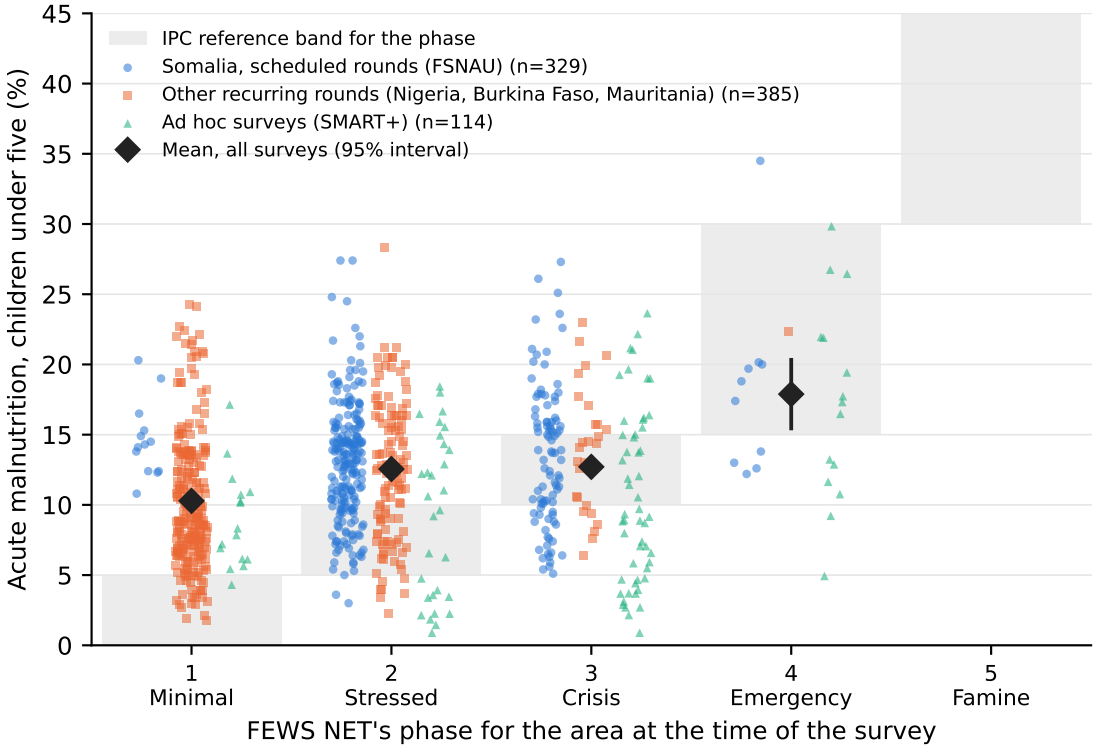

Figure 10: Measured acute malnutrition by FEWS NET phase. Each point is one survey: global acute malnutrition (weight-for-height) among children under five, against the phase FEWS NET's map gave the area at the time of the survey (rounded mean over the FEWS NET units in the survey area; points jittered). Grey boxes: the IPC reference band for each phase. Blue: Somalia's scheduled FSNAU rounds, rural zones, 2011–2024. Orange: other recurring national or sub-national rounds (Nigeria's UNICEF rounds, 2023–26; Burkina Faso and Mauritania national rounds, 2003–18). Green: ad hoc surveys in the SMART+ dashboard, 2022–26. Diamonds: mean of all surveys in the phase, with 95 percent intervals.

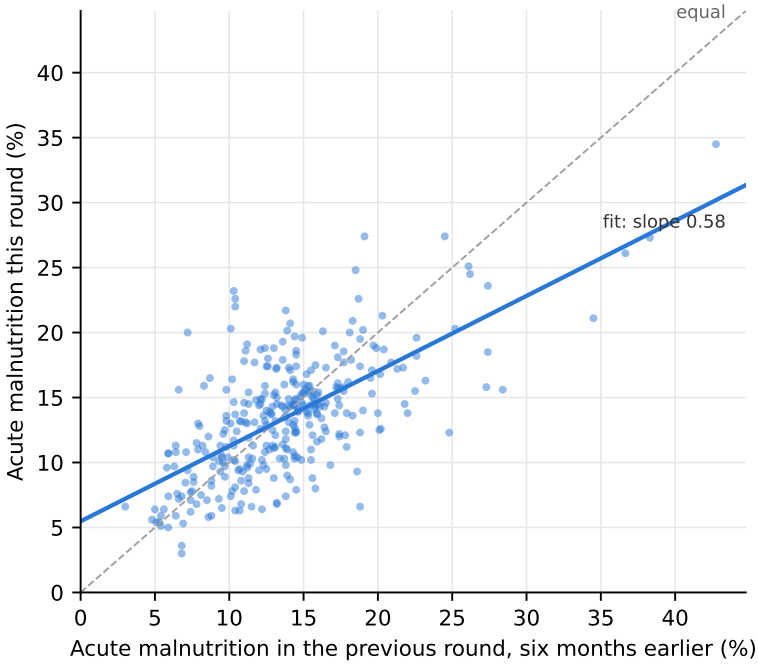

Figure 11: Somalia's scheduled surveys: acute malnutrition in a rural zone this round against the same zone six months earlier, 329 zone-seasons, 2011–2024. Solid line: least-squares fit; dashed line: equality.

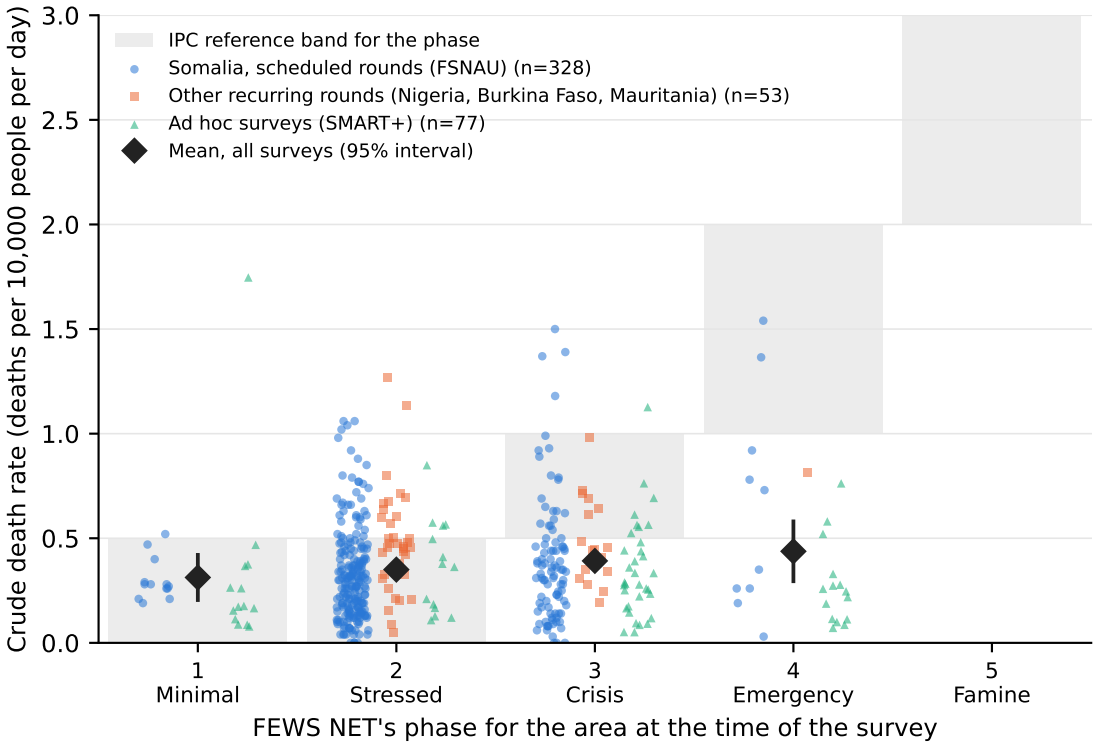

Figure 12: Measured crude death rates by FEWS NET phase. As Figure 10, for crude death rates (deaths per 10,000 people per day), in surveys that measured mortality. Grey boxes: the IPC reference band for each phase.

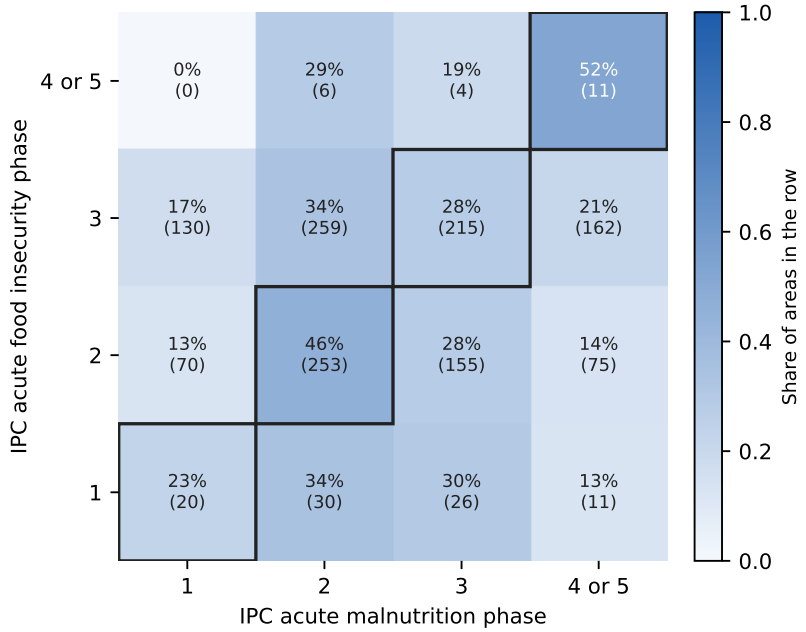

Figure 13: The IPC's two scales for the same areas. Rows: the IPC acute food insecurity phase of the area; columns: its acute malnutrition phase for the same period (published by the IPC, or classified from published acute malnutrition prevalence using the IPC's thresholds). Each cell gives the share of the row and the number of areas; outlined cells are where the two scales agree. 1,427 areas in Afghanistan, the Central African Republic, Cameroon, the Democratic Republic of Congo, Mali, Mozambique, Nigeria, Somalia and South Sudan, 2021–2026 (years vary by country).

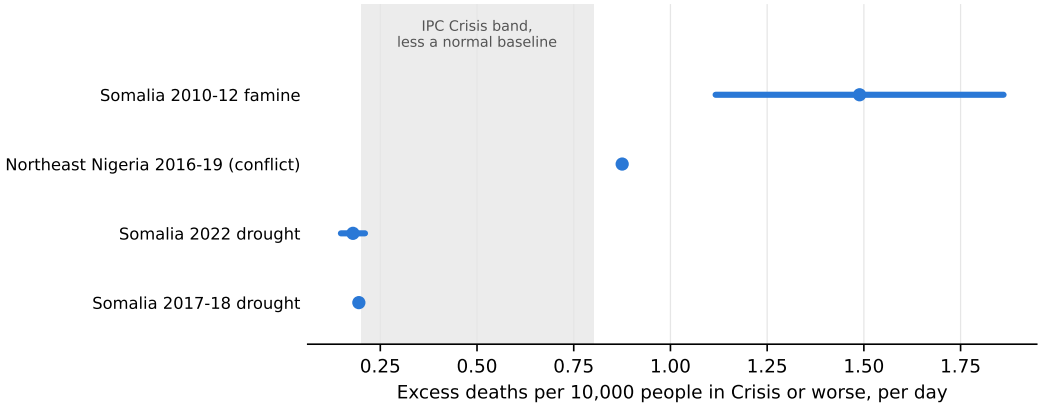

Figure 14: Excess deaths in documented crises, per person in Crisis or worse. Estimated excess deaths divided by the number of people classified in IPC or Cadre Harmonisé Phase 3 or worse and the length of the crisis; ranges reflect ranges in the death toll and in the Phase 3+ population. Grey band: the IPC Crisis band for crude death rates (0.5–1 per 10,000 per day) less a normal baseline of 0.2–0.3. Sources: Warsame et al. (2023); London School of Hygiene & Tropical Medicine et al. (2023); Checchi et al. (2023); Checchi and Robinson (2013).

for famine since 2017 have mostly been between 0.3 and 1.9, below the IPC's famine threshold of 2 (IPC Famine Review Committee, 2022, 2024). Arithmetic with the IPC bands would have predicted roughly two to five times the excess deaths estimated for Somalia in 2022.

8.6 A calibration

Table 4 summarizes the evidence and the values we use in Section 9. For each step from one phase to the next below Famine, we use 0.15 extra deaths per 10,000 per day (range 0.07–0.25) and 1.5 points of acute malnutrition (range 0.6–2.5). For the step from Emergency to Famine, where the evidence comes from famines with a late response, we use 1.5 extra deaths (range 0.9–1.9). The central values are a fifth to a half of what the IPC bands imply for ordinary steps, and the low end of the range comes from Somalia's scheduled surveys, the most selection-free evidence we have.

Table 4: What one phase means: evidence and the values used in the benefit-cost calculation

Evidence	Acute malnutrition (points per phase)	Crude death rate (per 10,000 per day, per phase)
IPC reference bands, midpoints (Stressed to Crisis; Crisis to Emergency)	5; 10	0.45; 0.75
Somalia, scheduled surveys, within zones	0.5–0.8	0.08–0.12
SMART+ surveys, country-by-year effects	1.8	0.00 (FEWS NET); 0.17 (IPC/CH)
Nigeria recurring rounds; Burkina Faso and Mauritania rounds	2.7; 3.3	–
Excess deaths per person in Crisis or worse: Somalia 2017–18, 2022	–	0.15–0.2
Excess deaths per person in Crisis or worse: famines with late response	–	0.9–1.9
Used below Famine (central; range)	1.5; 0.6–2.5	0.15; 0.07–0.25
Used from Emergency to Famine	–	1.5; 0.9–1.9

Notes: Survey estimates are slopes of the measured outcome on the phase; Somalia within-zone estimates with zone effects, with and without season effects. IPC reference bands: differences between band midpoints. Excess deaths per person in Crisis or worse are estimated excess deaths divided by the person-days in IPC Phase 3 or worse; see text for sources.

9 What is FEWS NET worth? A rough benefit-cost calculation

The evidence so far is about information and money, not lives. This section pushes it as far as it will go toward a cost per death averted, using five pieces. Each is uncertain, and we show how the answer moves with each. The calculation is a guide to orders of magnitude, not an estimate of causal effects.

1. Cost. Federal contract records show FEWS NET's cost directly (USAspending.gov, 2026). Obligations under FEWS NET's contracts averaged $37 million a year over fiscal years 2017–2024 and $44 million over 2019–2023. They are lumpy, ranging from $22 million to a peak of $63 million in fiscal 2023, when several new task orders were funded up front; that peak is the source of a widely reported figure of $64 million a year (NPR, 2025). About two-thirds of the money goes to field analysis — the maps and forecasts — through the main task order ($139 million over 2019–2024). The rest pays for the data hub, livelihood baseline studies, strategic planning and technical support at the U.S. Geological Survey's satellite data center. Interagency agreements with U.S. science agencies are not in the contract records and add a few million dollars more. We use $45 million a year as the central figure and $35–65 million as a range.

2. FEWS NET's word on what aid prevents. We take FEWS NET's aid flag at face value: in every area-round it flags, aid keeps the area one phase better than it would otherwise be. Between 2011 and 2024, FEWS NET flagged 11,671 area-rounds. We attach a population to each flagged area using WorldPop's 2020 gridded estimates (WorldPop, 2020), and count the months until the next map. On average, 28 million people lived in a flagged area at any time. Half of the flagged area-rounds (50 percent) were in Stressed held back from Crisis, and 42 percent were in Crisis held back from Emergency.

3. What a phase means. We use the calibration from Section 8. Each step from one phase to the next below Famine adds 0.15 deaths per 10,000 people per day (low 0.07, high 0.25) and 1.5 points of acute malnutrition among children under five (low 0.6, high 2.5); the step from Emergency to Famine adds 1.5 deaths (low 0.9, high 1.9). In the official IPC and Cadre Harmonisé data, 10 percent of people in an area classified as Stressed are themselves in Crisis or worse; the figure is 34 percent in Crisis areas and 60 percent in Emergency areas.

On FEWS NET's own account, then, aid in its flagged areas averts 80,000 (low), 168,000 (central) or 274,000 (high) deaths a year, and keeps about 6.5 million people a year out of Crisis or worse. Taking the IPC reference bands literally instead would give 121,000 to 820,000 deaths a year. For scale, the 2011 Somalia famine killed an estimated 258,000 people over two years (Checchi and Robinson, 2013); the IPC bands imply that aid prevents a disaster of that size every six months, which the evidence in Section 8 does not support.

4. FEWS NET's share of that aid. Not all of this aid is due to FEWS NET. We credit FEWS NET only with the aid that follows its distinctive information. That is the part of its forecast that the country's usual situation, the season, rainfall, conflict and prices — and, in one version, the latest official analysis — cannot predict (Sections 6 and 7). If funding rises by β log points per unit of this contribution x for a country and round, the share of funding due to FEWS NET is $1-e^{-\beta x}$. Where FEWS NET was less alarmed than other information ($x < 0$), it lowered funding. We then count $-(1-e^{\beta x})$: the funding it subtracted, as a share of what there would have been without it. Both branches measure FEWS NET's effect as a share of the larger of actual and counterfactual funding, so over- and under-alarm count equally. The funding responses β come from Table A1: 10 to 28 percent more funding per 10 percentage points.

This is the right counterfactual for a funding decision. Without FEWS NET, donors would still know that Somalia and South Sudan are chronically in crisis, and when the lean season falls; they would lose what FEWS NET tells them beyond that. Crediting FEWS NET with its whole forecast instead — as if donors would otherwise know nothing — gives $350–1,900 per death averted, but we regard that as an implausible upper bound.

5. Result. Table 5 and Figure 15 combine the pieces. FEWS NET's distinctive information accounts for 0.3–0.4 percent of the aid in its flagged areas: 0.3 to 0.4 percent of all humanitarian funding, and 0.3 percent of food and nutrition funding. Applied to the aid that FEWS NET says is holding back crises, this gives:

- **Deaths:** 290–970 averted a year, or $46,000–150,000 of FEWS NET's budget per death averted ($36,000–220,000 across the budget range). That is an order of magnitude more than the $3,000–5,500 of the most cost-effective charities (GiveWell, 2024b).
- **Hunger:** 41,000–110,000 person-years in Emergency or worse averted a year, at $400–1,100 each, and 17,000–28,000 person-years in Crisis or worse, at $1,600–2,700 each.[2]

[2]Fewer person-years are kept out of Crisis than out of Emergency because FEWS NET's distinctive information

Table 5: A rough benefit-cost calculation: FEWS NET credited with its distinctive information

FEWS NET credited with its distinctive information on:	Share of aid attributed	Deaths averted per year			Person-years out of Emergency+ per year	Child-years of acute malnutrition per year
		Low	Central	High		
All humanitarian funding; beyond data and official analyses	0.3%	290	460	520	41,000	66–160
All humanitarian funding; beyond data	0.4%	440	750	970	56,000	120–370
Food and nutrition funding; beyond data	0.3%	420	540	380	110,000	16–60
Cost per outcome averted (US$, budget $45 million a year)						
All humanitarian funding; beyond data and official analyses		150,000	99,000	87,000	1,100	270,000–680,000
All humanitarian funding; beyond data		100,000	60,000	46,000	800	120,000–380,000
Food and nutrition funding; beyond data		110,000	84,000	120,000	400	750,000–2,800,000

Notes: Areas FEWS NET flagged as held back by aid, 2011–2024, annual averages; aid assumed to keep each area one phase better. Population: WorldPop 2020. Deaths averted: population × months until the next map × the change in crude death rate from one phase, under the low, central and high calibrations of Table 4: 0.07, 0.15 and 0.25 deaths per 10,000 per day for each step below Famine, and 0.9, 1.5 and 1.9 from Emergency to Famine. Person-years out of Emergency or worse: from the average share of people in Emergency or worse in official IPC and Cadre Harmonisé areas of each phase. Child-years of acute malnutrition: children under five (17 percent of the population) × the change in acute malnutrition prevalence per phase (0.6–2.5 points; range across calibrations). Share of aid attributed: $1 - e^{-\beta x}$ for $x \geq 0$ and $-(1 - e^{\beta x})$ for $x < 0$, where x is FEWS NET's forecast beyond what the country, season, rainfall, conflict and prices (and, in the first row, the latest official analysis) predict, and β the within-country funding response (Table A1); averaged over flagged areas weighted by deaths averted under the central calibration. Costs: $45 million a year divided by each outcome.

- **Child malnutrition:** 50–240 child-years of acute malnutrition averted a year under the central calibration, at $190,000–910,000 each.

The shares are small partly for a mechanical reason. FEWS NET's forecasts assume the aid that is coming, so where aid is flowing — exactly the flagged areas — they tend to sit *below* what other information would predict, and FEWS NET's distinctive information looks like less alarm, not more. This matters most in the half of flagged areas that were Stressed and held back from Crisis. Under the IPC bands' most conservative reading, those areas carry no deaths; under the evidence-based calibration, they carry as many as the areas held back from Emergency, and FEWS NET's less alarmed signal there offsets much of what it adds elsewhere. Applying the one-sided formula $1 - e^{-\beta x}$ to negative signals as well nets out below zero.

The IPC bands as a sensitivity check. With the IPC reference bands instead of the evidence-based calibration, FEWS NET's distinctive information averts 3,100–12,000 deaths a year, at $3,700–15,000 per death. That range is around the cost per death of the most cost-effective charities. But it rests on death rates per phase several times higher than those measured (Section 8), so we do not treat it as the main estimate.

The calculation leaves out a good deal in both directions.

- **Ways it may overstate.**
  - It takes FEWS NET's flags at face value, though nearly half of the flags on failed warnings predate the warning, and within Somalia and Sudan the flags track where aid partners work only loosely (Section G).
  - Aid that FEWS NET steers may come from other crises where it would also have saved lives. If the displaced aid would have done half as much good, the costs double.

is, on balance, slightly *less* alarmed than other information in Stressed areas held back from Crisis, which pulls down the Crisis total.

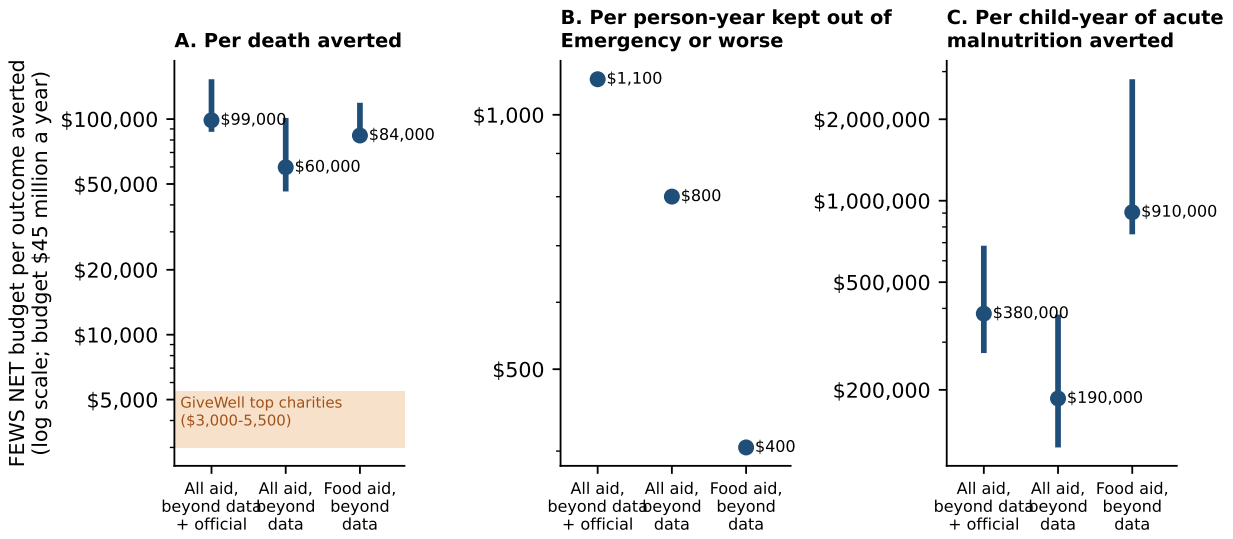

Figure 15: What FEWS NET's budget buys, crediting it only with its distinctive information. Cost per outcome averted, at $45 million a year, for the aid that follows FEWS NET's forecasts beyond what each country's usual situation, the season, rainfall, conflict and prices predict ("beyond data"), or these plus the latest official analysis ("beyond data + official"), using all humanitarian funding or food and nutrition funding. Dots: central calibration of deaths and malnutrition per phase (Section 8). Bars: range across the low, central and high calibrations. Shaded band: GiveWell's estimate of the cost per death averted by its top charities (GiveWell, 2024b).

  - The funding responses are associations, not causal effects, and the within-country evidence for Somalia and Sudan does not show located aid responding to FEWS NET's distinctive information (Section G).

- **Ways it may understate.**
  - FEWS NET's forecasts assume planned aid, which biases its distinctive information downward exactly where aid is flowing.
  - The calibration of deaths per phase leans on Somalia's scheduled surveys, which underrepresent the worst-hit areas, and on phase measures noisy enough to bias the slopes toward zero.
  - It counts only flagged areas. Crises that warnings prevent entirely never show up, nor do responses by governments, markets and households.
  - It ignores FEWS NET's value beyond aid allocation, for example to governments, researchers and the official classifications to which its analysts contribute.

With those caveats, the calculation puts FEWS NET's distinctive information well below the most cost-effective global health charities in lives saved: $46,000–150,000 per death averted, against $3,000–5,500. Measured in food insecurity rather than lives, it does better, at about $400–1,100 per person-year kept out of Emergency. The gap between the two is the central lesson of Section 8: a phase of food insecurity is worth far fewer deaths than the IPC bands suggest.

In a philanthropic funder's units. Coefficient Giving, a philanthropic funder, compares grants across causes on a common scale (Open Philanthropy, 2021). The unit is the value of giving $1 to someone earning $50,000 a year, and welfare is assumed to rise with the logarithm of income. Raising one person's income by 1 percent for a year is therefore worth about $500, and a year of healthy life (a disability-adjusted life year, or DALY) is worth $100,000. A grant clears the funder's bar if it returns roughly 1,000 times its cost in these units, which for health means averting about one DALY per $100 spent. Averting a death counts as the DALYs it saves. Famine deaths fall heavily on young children, so we assume 30–55 DALYs per death, with 40 as the central case. On that basis FEWS NET's distinctive information returns 26–87 times its cost across the specifications and mortality scenarios in Table 5. The range is 20–65 times at 30 DALYs per death and 36–120 times at 55, and 28–86 times across the budget range at the central assumptions. Hunger short of death adds little. Valuing each person-year kept out of Emergency as a 10–25 percent gain in consumption adds 4–28 times. The bar corresponds to about $4,000 per death averted. On these numbers FEWS NET's distinctive information sits an order of magnitude below the bar. With the IPC bands instead, it would return 270–1,100 times its cost, around the bar. Crediting FEWS NET with its whole forecast would give 2,100–11,000 times, which illustrates how much the answer rests on the counterfactual.

10 Which parts of FEWS NET are worth paying for?

The choice facing funders is not only whether to pay for FEWS NET as a whole. FEWS NET bundles several things: field analysts who produce maps and written reports, market price monitoring, and the use of nutrition and mortality surveys run by other agencies. A funder could keep some pieces and not others, or pay to strengthen one. This section asks which of them carry information that improves forecasts. We use two exercises: a pilot that turns FEWS NET's written reports into data, and a test of how much market prices add.

10.1 The written reports

FEWS NET publishes far more than maps. Each outlook sets out the assumptions behind the forecast, a worst case, the aid expected and the data the analysts relied on, and updates, key messages and alerts follow between rounds. If the maps compress this reasoning too far, the text might hold early signs of the step FEWS NET forecasts worst, from Crisis to Emergency (Section 4).

We tested this for Somalia, Ethiopia and Sudan, 2011–2024. We downloaded all 502 of FEWS NET's reports for these countries, including 135 full outlooks, and used a large language model (Claude) to turn each into structured records. For each area discussed, we recorded the phases stated now and for the projection, any worst case, the expected direction, the drivers named, the status of aid and any statement that data were missing. We also recorded every survey result the report quotes. The model was told to record only what each report says. This matters because the model knows how these crises turned out. Recording stated facts is safe, but asking the model

to forecast past crises would not be. Each area is matched to FEWS NET's mapping units by name. As a check, where a report names a district or livelihood zone, the current phase it states lies within the phases on FEWS NET's map for those units in 91 percent of 322 cases.

The text adds little to the maps. Of 8,564 area-rounds in Crisis, 744 reached Emergency on the next map; FEWS NET had forecast Emergency for 32 percent of them. We add everything extracted from the reports to FEWS NET's forecast and aid flags: projected Emergency, worst cases, expected deterioration, expected cuts in aid, access constraints, the drivers named and statements of uncertainty. The cross-fitted AUC for escalation does not rise (0.60 with the map alone, 0.59 with the text). Scored by need, it barely moves (0.71 to 0.73). Within country and round, two features of the text are associated with escalation (Appendix Table A2). Areas where a report expected aid to fall, or said access was constrained, were 6 and 7 percentage points more likely to reach Emergency, against a base of 8.7 percent. Both concern the assumption that planned aid will arrive, which FEWS NET's forecasts build in. But neither improves out-of-sample prediction by more than a hundredth of AUC. The same analysts write the reports and draw the maps, and the two mostly say the same thing. What FEWS NET knows is largely already in its maps. Mining its reports is not a route to much better forecasts, though where its reports doubt the aid pipeline, its forecasts deserve less confidence.

10.2 Surveys

The reports do contain something the maps do not: the results of nutrition and mortality surveys. These are mostly standardized SMART surveys run by UNICEF, NGOs and national partners, and in Somalia by the FAO-managed Food Security and Nutrition Analysis Unit. We extracted 263 distinct survey results (188 in Somalia, 52 in Ethiopia and 23 in Sudan). They measure outcomes independently of any phase classification. Mean acute malnutrition among children under five rises with FEWS NET's phase at the time of the survey: 19 percent in Stressed areas, 22 percent in Crisis, 31 percent in Emergency and 39 percent in Famine. The reports quote surveys selectively, and 86 percent of those quoted show acute malnutrition of 15 percent or more. So these results cannot score FEWS NET's accuracy, but they show its phases track measured malnutrition.

Survey coverage is uneven. Among area-rounds that FEWS NET mapped as Emergency, the reports quote a survey from the previous 12 months for 67 percent in Ethiopia, 54 percent in Somalia and 14 percent in Sudan. These are lower bounds, since the reports do not quote every survey.

New surveys move the maps, and only upward. In 3.5 percent of area-rounds, a survey was carried out between FEWS NET's forecast and its next map. When one was, the next map was worse than the forecast 8.8 percentage points more often (standard error 3.1, against a base rate of 10 percent). This comparison is within country and round, holds the forecast fixed, and controls for everything the reports said about the area when the forecast was made. The next map was no more likely to be better than forecast (-0.7 points, standard error 3.0). Among areas in Crisis, a new survey raised the chance of moving to Emergency by 6.4 points (standard error 2.6) from a

base of 8.7 percent. A survey preceded 25 percent of the escalations FEWS NET had not forecast, 15 percent of those it had, and 6 percent of the cases in Crisis that did not escalate.

Three readings could explain this. Surveys may reveal deterioration that the forecast missed. The IPC's rules may cap classifications without survey evidence, so that a survey can unlock a higher phase but its absence rarely pulls one down. Or surveys may be sent where people on the ground already suspect trouble, for reasons the reports do not state. Two checks favor the third reading. First, the rules do not explain it. The IPC requires nutrition and mortality evidence to classify Famine, and weighs it heavily for Emergency, but not for Crisis. Yet among areas forecast to be Stressed or better, a new survey raised the chance that the next map showed Crisis or worse by 7.5 percentage points (standard error 2.5, base rate 11 percent). Second, what the survey found matters little. Surveys showing acute malnutrition below 15 percent (271 area-rounds) raised the chance of a worse map by 14.8 points (standard error 4.7), about as much as surveys showing 15 percent or more (11.9, standard error 4.6). If surveys moved the maps through their content, reassuring results would pull them down. Instead they made a better-than-forecast map less likely, not more (-8.6 points, standard error 3.7).

So the decision to survey is itself the signal. Agencies send survey teams where conditions are slipping, and FEWS NET's next map moves with them. This tells us two things. First, the people who commission surveys know something FEWS NET's forecasts do not yet reflect. A record of where surveys are planned and why could serve as an early warning in its own right. Second, comparing places with and without surveys cannot show what better survey coverage would add to forecasts, because surveys are not placed at random. That question needs surveys whose timing is fixed in advance, such as scheduled seasonal assessments, so that their results, not the decision to collect them, can be scored. Section 8 uses Somalia's scheduled surveys to do this.

10.3 Market prices

FEWS NET's data warehouse publishes retail prices from 881 markets that it monitors itself or compiles from government systems, beyond those it takes from WFP; 77 percent of its staple price records are not from WFP. For each area and round, we take 3- and 12-month changes in staple prices at the nearest reporting market within 150 kilometers. WFP and FEWS NET both have a price series for 51 percent of area-rounds, only WFP for 22 percent, only FEWS NET for 16 percent, and neither for 11 percent. FEWS NET's own monitoring fills WFP's gaps in Kenya, Guatemala, parts of Sudan, and Ethiopia in 2016–2019. WFP's data are better in the Sahel, where FEWS NET's prices are not public.

Prices add little to forecasts from either source. We predict which areas tip into Crisis, or escalate from Crisis to Emergency, at the next map, with cross-fitted models. Using only what a donor could see without FEWS NET — the country, the season, rainfall and political violence — the AUC for new crises is 0.725; adding both price series gives 0.727, while adding FEWS NET's map and forecast gives 0.901. For escalation the figures are 0.714, 0.714 and 0.817. Starting instead from FEWS NET's current and previous maps, prices move the AUC for new crises from 0.844

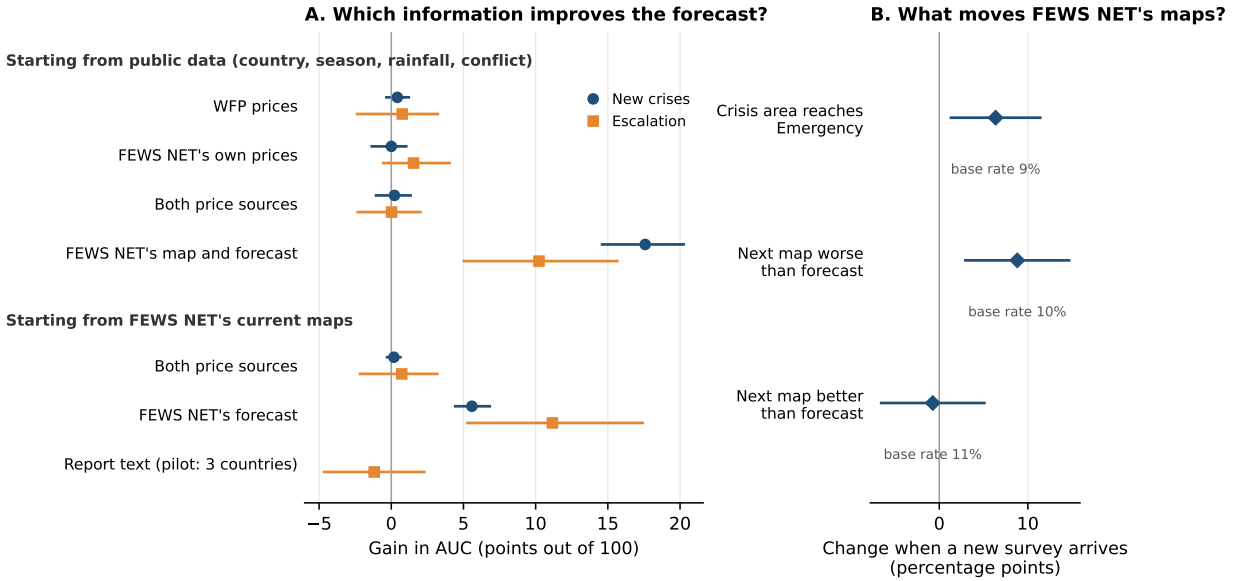

Figure 16: Which information improves forecasts of food crises? Panel A: gain in the cross-fitted AUC from adding each source of information, for areas tipping into Crisis or worse at the next FEWS NET map (circles) and for areas in Crisis escalating to Emergency or worse (squares), FEWS NET areas 2011–2024. Public data: country, calendar month, forecast horizon, rainfall (CHIRPS) and political violence (ACLED). Prices: 3- and 12-month changes in retail staple prices at the nearest market within 150 km, from WFP or from FEWS NET's own price monitoring and the government systems it compiles. Report text: features extracted from FEWS NET's written reports, Somalia, Ethiopia and Sudan only. Lines are 95 percent intervals from resampling country-years. Panel B: change in the probability of each outcome on the next map when a nutrition or mortality survey is carried out between FEWS NET's forecast and that map, Somalia, Ethiopia and Sudan, with country-by-round fixed effects and controls for the forecast and for everything the reports said about the area at the time; 95 percent intervals clustered by region.

to 0.846 and for escalation from 0.711 to between 0.719 and 0.738, against 0.900 and 0.823 with FEWS NET's forecast. Price changes, taken on their own, carry little of the signal FEWS NET adds. That does not mean prices are worthless: FEWS NET's analysts use them, along with trade flows, terms of trade and household purchasing power, and we cannot test what their judgment would be without them.

Figure 16 brings the forecasting results together. Panel A shows how much each source of information raises the AUC, starting either from what a donor could see without FEWS NET or from FEWS NET's current maps. Prices and report text add nothing distinguishable from zero. FEWS NET's own map and forecast add 18 points over public data for new crises and 10 for escalation, and its forecast adds 6 and 11 points over its current maps. Panel B shows the one input that does move FEWS NET's maps: new survey results.

10.4 What this means for funding

The evidence points to three conclusions about the pieces. First, the value lies in the analysts' judgment, not in any data series a funder could buy separately. The part of FEWS NET's forecasts that

public data cannot reproduce is the part that is borne out by independent assessments (Section 6) and the part that money follows (Section 7). Neither prices nor the written reports add much to it. Second, price monitoring is partly duplicative: WFP covers most of the same ground, and together the two leave about one area-round in nine without a nearby price series. FEWS NET's own price monitoring matters most where WFP's is thin. Third, the input most clearly missing is outcome measurement in crisis areas. New surveys are what most often change FEWS NET's classifications, and they are scarcest where crises are hardest to reach. Where surveys are fielded on a schedule, as in Somalia, last season's results predict where children will be malnourished next season far better than FEWS NET's forecasts do; FEWS NET's phases carry little information about malnutrition or child mortality. Without such surveys there is also no way to check, afterward, how bad a crisis was. Sudan, where famine was confirmed in 2024, is the clearest case. Household data collection by humanitarian agencies has also been cut since 2025 (Kenny, 2026a). This is where the case for independent, repeated surveys in areas at Crisis or worse (Kenny, 2026b) meets the case for early warning. The same data would make responses possible to evaluate, and, if collected on a schedule, would add the nutrition and mortality signal that phase classifications lack.

11 Would paying for surveys pay off?

If FEWS NET as a whole looks below the bar in lives saved, would more surveys look better? Surveys of acute malnutrition and mortality cost about $15,000–21,000 for each area estimated in sub-Saharan Africa, and up to $30,000 in harder settings (UNICEF and Action Against Hunger, 2016; Daher et al., 2018). Somalia's scheduled programme surveys about 12 rural zones a season, plus towns and displaced settlements. For surveys to save lives, a chain of links must hold:

1. more surveys give better information about where children are malnourished and dying;
2. that information makes warnings better, earlier, or simply louder;
3. better warnings move more aid, or move it to better places;
4. that aid reduces malnutrition and death.

The evidence on each link is uneven.

1. Information. Strong. In Somalia, last season's survey predicts this season's acute malnutrition far better than FEWS NET's forecast (Section 8). No other source we examined substitutes for it, and models that try to predict malnutrition without surveys have performed poorly (Checchi et al., 2022).

2. Warnings. Weak, through FEWS NET. FEWS NET's forecasts barely respond to survey results: a zone whose last survey showed 10 more points of acute malnutrition is forecast 0.09 of a phase worse (standard error 0.05). Ad hoc surveys move FEWS NET's maps upward whatever

they find (Section 10), which looks more like added alarm than added accuracy. FEWS NET's phases are about food insecurity, and survey results about malnutrition do not translate into them.

3. Aid. Mostly outside FEWS NET. Money follows FEWS NET's forecasts (Section 7), but surveys hardly shape those forecasts. Survey results reach aid more directly: nutrition programmes size their caseloads and supplies from survey prevalence, multiplying the number of children by the measured rate and a correction for new cases (Isanaka et al., 2021; Bongassie et al., 2021). How far donors follow such assessments is less clear (Olin et al., 2014).

4. Lives. Strong, for treatment. Treating severe acute malnutrition in the community is among the best-evidenced interventions in crises, at roughly $4,000–7,000 per death averted when we apply GiveWell's inputs for two well-run programmes (GiveWell, 2024a, 2025). But programmes reach a minority of cases; average coverage across 21 countries was 38 percent (Rogers et al., 2015).

A coarse targeting rule. A first, crude test asks whether surveys help a programme choose which half of the zones to serve each season. They barely do: choosing by predicted caseload, the survey-based choice covers 73 percent of the season's malnourished children and the forecast-based choice 73 percent, because where malnourished children are depends mostly on where children are. But a yes-or-no choice of zones wastes most of what surveys tell a planner.

If treatment followed surveys. The links that hold most firmly are the first and the last: surveys measure malnutrition, and treating it saves lives. What is missing is evidence that treatment follows surveys. So we ask the counterfactual directly: if a treatment programme used survey results as well as it could, what would one round of surveys be worth?

We model a planner in Somalia who, each season, has a fixed number of treatment places for acutely malnourished children in the 12 rural zones FSNAU surveys, and spends them to avert as many deaths as possible given what it can see. Each zone has two kinds of case. Severe acute malnutrition, about 16 percent of cases, carries an untreated one-year mortality of about 10 percent, which treatment cuts by about 70 percent; moderate acute malnutrition carries about 4 percent, cut by about 40 percent (GiveWell, 2024a). Caseloads are zone population times the share under five times measured prevalence times the standard correction for new cases (Isanaka et al., 2021), and at most 80 percent of a zone's cases can be reached. The planner sends places first where it predicts the most deaths averted per place, up to its predicted reachable caseload in each zone. Places sent to a zone with fewer cases than predicted are stranded; in two variants, half or all of them can be moved once the true caseload is known. The planner predicts each zone's severe and moderate prevalence in one of three ways: from the national average, from FEWS NET's forecast phase, or from the zone's previous survey; and we compare these with perfect foresight. All predictions are made out of sample.

Survey-based planning saves more lives at every realistic budget (Figure 17). With places for 38 percent of the caseload, the average coverage of treatment programmes, a planner using FEWS

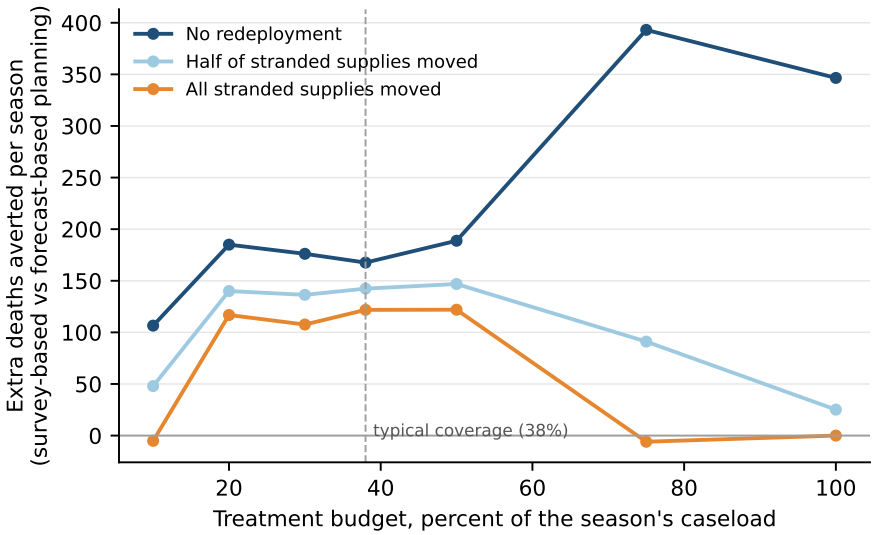

Figure 17: If treatment followed surveys: extra deaths averted per season in Somalia when a planner places treatment using each zone's previous scheduled survey rather than FEWS NET's forecast, by the size of the treatment budget. 12 surveyed rural zones per season over 26 seasons. The planner allocates treatment places to severe and moderate acute malnutrition by zone to maximize predicted deaths averted; places sent to zones with fewer cases than predicted are stranded, and none, half or all of them can be moved once caseloads are known. Mortality and treatment effects from GiveWell's inputs; caseloads from measured prevalence, population and the standard incidence correction.

NET's forecast averts about 5,651 deaths a season; one using the previous survey averts 168 more if stranded places cannot be moved, 142 more if half can, and 122 more if all can. That is 13–27 percent of the gain perfect foresight would bring. A planner who knows only population does about as well as one using FEWS NET's forecast. Most of the survey's value comes from knowing where severe cases are, so that places go to the children most likely to die; moving stranded supplies cannot undo that kind of misallocation. A round of surveys in these zones costs about $240,000, so the extra deaths averted cost about $1,400–1,900 each ($700–2,900 across survey costs and redeployment), and $1,200–2,200 across budgets of 20–50 percent of the caseload. The value disappears only at the extremes, when the budget is so small that it is spent on severe cases anywhere, or so large that nearly every case can be reached, and stranded supplies can all be moved.

This is an upper bound in one sense and a lower bound in another. It assumes treatment programmes act on survey results as well as they could, which is the point of the exercise but not current practice. It uses GiveWell's mortality inputs before its adjustments, and Somalia's surveyed zones only. But it values surveys only for placing treatment within a fixed budget. It gives them no credit for sizing that budget, for detecting famine conditions, or for evaluation.

What this implies. The case for paying for more surveys does not rest on better FEWS NET warnings: FEWS NET's phases do not carry the information that matters for treatment, and its forecasts barely respond to survey results. It rests on what surveys can do for the response directly. If treatment programmes placed their resources by survey results, a round of Somalia's surveys

would avert deaths at roughly $1,200–2,200 each, in the range of the most cost-effective charities and far cheaper than FEWS NET's distinctive information. Whether that value is realized depends on whether funders and programmes act on survey results, which in turn depends on surveys being regular, timely and public. Surveys also have value we do not count: sizing the response, seeing famine-level conditions directly, and knowing afterwards whether a response worked (Kenny, 2026b).

12 What the data cannot tell us

The ideal evaluation would compare welfare — child malnutrition, mortality — in places and times with and without FEWS NET. We tried two versions with the data available, and neither is informative.

The 2025 shutdown. FEWS NET went dark in January 2025 just as U.S. aid was cut. If its "held back by aid" flags are right, flagged areas should have deteriorated faster afterwards than comparable unflagged areas. Over 12 months, flagged areas worsen relative to comparable unflagged areas by about 0.20 of a phase in normal years. For windows ending in 2025, the gap widened by a further 0.09 phases on FEWS NET's own later maps (wild bootstrap $p = 0.43$) and 0.15 on official classifications ($p = 0.26$). The flag carries information about fragility, but the data cannot yet separate the cut's effect from the trend. We need outcomes beyond mid-2026 (Appendix C).

Changes in FEWS NET coverage. FEWS NET has entered and left countries over time, but these moves follow aid and conflict trends, so comparing levels before and after is confounded. A narrower test asks whether local shocks do less damage, within a country, when FEWS NET covers it. Local rainfall, conflict and price shocks explain only 1.7 percent of the variation in official classifications within country and month, and coverage does not change their effect (-0.009, standard error 0.018, before 2025). Classifications move too slowly, and too nationally, to detect FEWS NET's effect this way (Appendix D). The same weakness of public fundamentals appears in Section 7: they explain little of FEWS NET's forecasts within a country and season, which is why most of FEWS NET's information cannot be reproduced from public data.

Testing whether FEWS NET saves lives will require outcomes it does not produce: child anthropometry and mortality from household surveys, linked to the timing and location of its warnings.

13 Conclusion

FEWS NET rarely misses a food crisis outright, but it often sees emergencies late and one phase too mild. About half of its emergency warnings do not come true; FEWS NET credits aid for about half of those, though often aid that was already flowing. Measured against what donors could otherwise know, it adds information that independent assessments later bear out, it raises

fewer false alarms than the official projections, and humanitarian funding moves with the part of its forecasts that public data cannot reproduce.

For funders deciding FEWS NET's future, the relevant comparison is with what would replace it. In three-quarters of FEWS NET's coverage, there is no recent official analysis to fall back on, and the raw signals — rainfall, conflict, prices — predict where crises will strike much less well. FEWS NET's distinctive contribution is modest in any single forecast but systematic, and it is the part that money follows. Against a budget of about $45 million a year — a fraction of a percent of the humanitarian funding that flows to the countries it monitors — a rough calculation that credits FEWS NET only with its distinctive information, and takes its own judgments of what aid prevents at face value, puts its cost at $46,000–150,000 per death averted and $400–1,100 per person-year kept out of Emergency. As a way of saving lives, that is well below the best alternatives. The reason is less FEWS NET's skill than what it measures: a phase of food insecurity is worth far fewer deaths than the IPC's reference bands imply, and evaluations that use the bands, as this one first did, overstate the lives at stake by several times.

For funders choosing among pieces rather than the whole, the value lies in the analysts' judgment. Neither FEWS NET's written reports nor market price series add much to what its maps already say. The piece most clearly missing is outcome measurement: new nutrition and mortality surveys are what most often change FEWS NET's maps, and they are scarcest in places like Sudan, where they matter most. Paying for repeated surveys in areas at Crisis or worse would make it possible to tell, afterward, whether the response worked. In Somalia, where surveys already run on a fixed schedule, last season's results predict this season's child malnutrition far better than FEWS NET's forecasts, which barely track it at all. Warnings about food insecurity and warnings about malnutrition and death are different products, and only surveys supply the second. If treatment followed them, Somalia's surveys would avert deaths at roughly $1,200–2,200 each, by steering treatment to severe cases, before counting their value for sizing responses, seeing famine-level conditions directly and knowing whether a response worked. The binding constraint is not the surveys but whether the response acts on them.

Three changes would make the system easier to evaluate and probably more useful. First, publish a forecast without assumed aid alongside the current one. Donors need to know what will happen if they do nothing, and evaluators need it to separate crises prevented from false alarms. Second, record when and why the aid flag is applied, so that "held back by aid" can be distinguished from "aid was already there." Third, validate forecasts against independent outcomes. Our comparisons use the IPC and Cadre Harmonisé, which share analysts with FEWS NET; linking FEWS NET's warnings to household survey data on child malnutrition and mortality would show whether its information, and the aid it moves, change lives.

A Data construction

FEWS NET classifications. We download all current-situation ("CS") and projection ("ML1" near-term, "ML2" medium-term) classifications from the FEWS NET Data Warehouse, month by month, January 2011 to August 2026, and use those through December 2024. Each record gives an area identifier, its phase, the projection period and whether the area carries the aid flag. We use the full map rounds (three per year since 2016; quarterly before). For the analyses in Sections 6 and 7, the unit is an area and map round, giving 190,131 area-rounds for 16,053 areas in 28 countries with complete forecasts and a next map within eight months.

Official classifications. Cadre Harmonisé records (current and projected) come from the regional dataset; IPC records from the IPC's area-level data (2017–2026). For IPC records we derive the area phase from population shares using the IPC's 20 percent rule. Areas are matched to polygons from the Cadre Harmonisé 2023 map, IPC country maps and geoBoundaries administrative units, and overlaid on FEWS NET's areas in an equal-area projection. FEWS NET's classifications are averaged over each official area, weighted by overlap.

Raw signals. Rainfall is the area mean of monthly CHIRPS rainfall. Conflict is ACLED's district-level political violence data, available sub-nationally for the 19 countries with UN humanitarian response plans. Districts are matched to OCHA administrative boundaries by district code, then by name, and apportioned to FEWS NET areas by area share. Prices are the mean 3- and 12-month log changes of retail cereal and tuber prices at the WFP market nearest each FEWS NET area, within 150 km.

Funding. Humanitarian commitments ("paid" and "commitment" status, incoming flows) from the Financial Tracking Service, assigned to recipient countries; multi-country flows are dropped. Food and nutrition funding is the subset whose cluster is Food Security or Nutrition.

Prediction models. All benchmark predictions use gradient-boosted trees (scikit-learn's histogram gradient boosting) with country as a categorical feature, cross-fitted by year: predictions for each year come from a model trained on all other years.

B The masking test

If aid prevents crises that FEWS NET warns about, its distinctive warnings should be borne out less often when funding to the country rises unexpectedly. Funding surprises are country-round residuals of log funding over the next six months, after removing country and time effects and the country's funding in the previous six months. We split country-rounds into thirds and estimate, within each third, how much of FEWS NET's distinctive warning (the forecast minus its prediction from raw signals and previous maps) is borne out on its next map, with country-by-round fixed

effects. Figure A1 shows no pattern: the share is about one half in all three groups, whether outcomes are scored as mapped or by need. The interaction of the distinctive warning with the funding surprise is 0.009 (standard error 0.028).

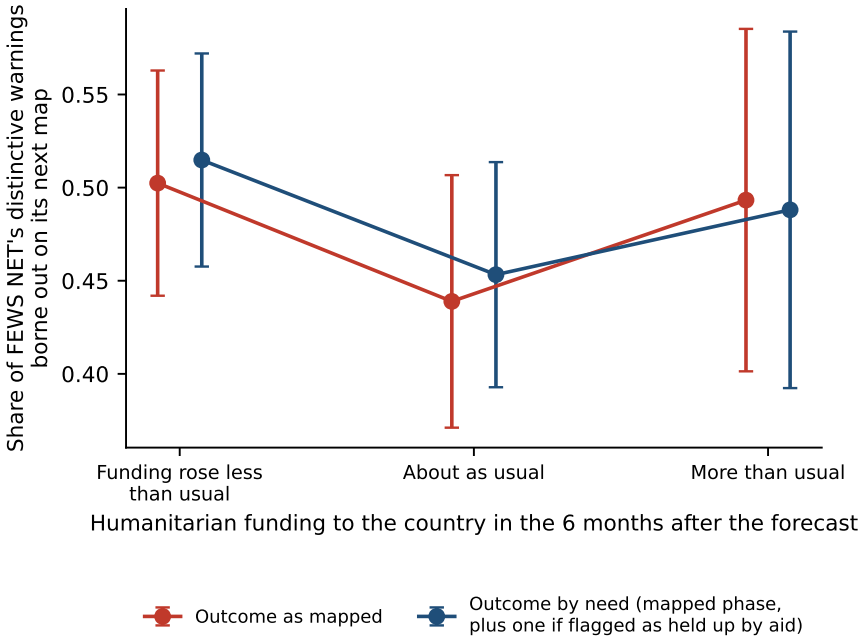

Figure A1: Do warnings come true less often where money flowed? Coefficient on FEWS NET's distinctive warning (forecast of Crisis or worse minus its out-of-sample prediction from rainfall, conflict, prices, previous maps, country and season) in a regression of Crisis or worse on its next map, by the country's funding surprise over the following six months. Red: outcome as mapped. Blue: outcome by need (mapped phase plus one if flagged as held up by aid). 95 percent intervals clustered by country.

C The 2025 shutdown

We compare same-season changes in areas FEWS NET flagged as held up by aid with unflagged areas that started in the same phase, country and month, for 12-month windows ending each year from 2014 to 2025. Windows ending in 2025 span the shutdown and the U.S. aid cut; earlier windows show how flagged areas normally evolve. Figure A2 shows that flagged areas worsen relative to unflagged ones in almost every year, and that the gap was already rising in 2023–2024, when humanitarian funding was falling. The 2025 gap is in line with that trend. Using 24-month windows produces a larger 2025 gap that is not repeated in 2026; pooling horizons, as in an earlier version of this analysis, mixes windows of different lengths in different years and overstates the effect.

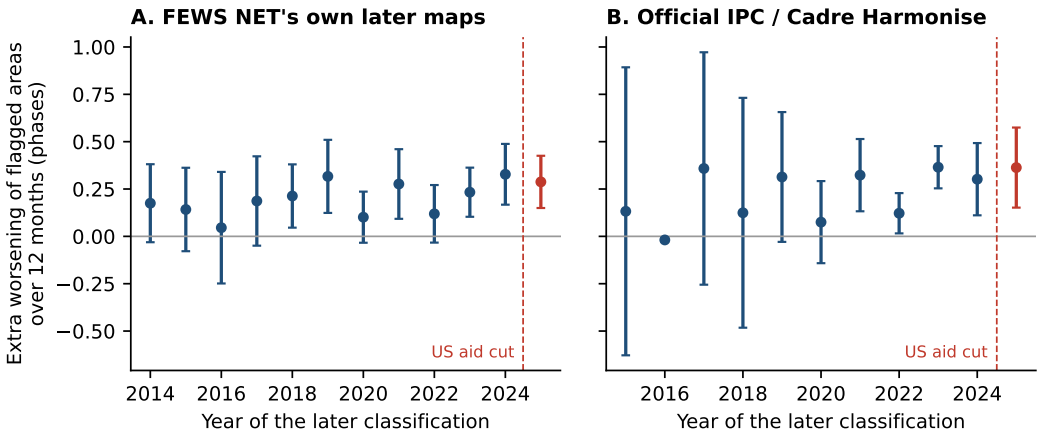

Figure A2: Did areas FEWS NET flagged as held up by aid deteriorate after the 2025 shutdown? Difference in the 12-month change in phase between flagged and unflagged areas that started in the same phase, country and month, by the year the window ends. Panel A: FEWS NET's own maps (FEWS NET areas in Phase 2–3). Panel B: official IPC and Cadre Harmonisé analyses, with the flag measured as the share of the official area covered by flagged FEWS NET areas in a map made at most four months before. Red: windows ending after the shutdown. 95 percent intervals clustered by country.

D Coverage changes and local shocks

We built an index of local shocks — rainfall deficits, political violence and food price spikes, weighted to predict official classifications in other countries — and asked whether its effect on official classifications differs, within a country, between periods when FEWS NET covered the country and periods when it did not. With area and country-by-month fixed effects and country-specific shock effects, the interaction is −0.009 (standard error 0.018) before 2025 and −0.002 (0.002) in 2025–2026, measured on the share of the population in Crisis or worse. The index explains only 1.7 percent of the within-country variation in classifications; rainfall alone explains 0.06 percent. An earlier specification suggested that shocks did *more* damage under FEWS NET coverage; that result rested entirely on Cameroon, where FEWS NET arrived in 2020 as conflict escalated, and on archive gaps that made FEWS NET appear to leave Burkina Faso and Mauritania when it had not.

E Funding regressions

Table A1: Humanitarian funding and FEWS NET's maps and forecasts, within countries

	Map vs forecast		Beyond rainfall, conflict and prices		Beyond rainfall, conflict, prices and official analysis	
	All	Food	All	Food	All	Food
	(1)	(2)	(3)	(4)	(5)	(6)
Share of areas in Crisis+, current map	−1.0	−1.8				
	(4.0)	(6.7)				
Share of areas forecast in Crisis+	10.0***	22.1**				
	(3.8)	(8.6)				
Forecast: part predictable from country, season and shocks			3.1	9.7	6.7	16.3
			(6.7)	(14.5)	(6.2)	(12.8)
Forecast: FEWS NET's own contribution			11.2***	28.3***	10.2***	26.9***
			(3.9)	(9.3)	(3.6)	(9.4)
Country × map rounds	968	967	851	850	851	850
Countries	37	37	28	28	28	28

Notes: Country × FEWS NET map round, 2011–2024. Outcome: log humanitarian funding committed to the country over the six months after the map (OCHA Financial Tracking Service); all humanitarian funding ("All") or food security and nutrition ("Food"). Coefficients are scaled to log points per 10 percentage points of the country's FEWS NET areas (approximately the percent change). Columns 1–2: share of areas in Crisis or worse on the current map and in the medium-term forecast, in the same regression. Columns 3–6: the forecast share split into its out-of-sample prediction from rainfall, conflict, prices, country and season (columns 3–4), or these plus the latest official analysis (columns 5–6), and FEWS NET's contribution beyond that prediction. All columns include country and time fixed effects and log funding in the previous six months. Standard errors clustered by country in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

F FEWS NET's reports and escalation

Table A2: Do FEWS NET's reports predict escalation from Crisis to Emergency beyond its maps?

	Emergency+ on next map			Emergency+ by need		
	(1)	(2)	(3)	(4)	(5)	(6)
FEWS NET forecast: Emergency	0.245***	0.242***	0.245***	0.408***	0.409***	0.406***
	(0.040)	(0.037)	(0.036)	(0.062)	(0.062)	(0.060)

Notes: Linear probability models. Sample: FEWS NET areas in Crisis (Phase 3) at map round r, Somalia, Ethiopia and Sudan, 2011–2024, in rounds with at least one extracted report. Outcome: Emergency or worse on the next map (columns 1–3), or by need, the mapped phase plus one if flagged as held back by aid (columns 4–6). "Report" variables are indicators that a FEWS NET report published in the four months up to r said this about the area (extracted with a large language model and matched to mapping units by name). Survey variables refer to survey results quoted in reports, fielded in the 12 months before r. All columns include country-by-round fixed effects. Standard errors clustered by region (first administrative level) in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

G Aid and FEWS NET within Somalia and Sudan

Humanitarian funding data are recorded by country, so Section 7 could ask only whether a country's funding moves with FEWS NET's view of the country. The benefit-cost calculation also rests on FEWS NET's district-level judgments of where aid is holding crises back. Neither can be checked without aid data below the country level. Such data exist only from about 2014, and best for Somalia and Sudan. We use three kinds.

- **Money:** allocations from the UN's country-based pooled funds, which record each project's budget by district and sector. They are small, about 3–5 percent of humanitarian funding, but they are allocated by OCHA with explicit geographic priorities, so they test whether the system's own targeting follows FEWS NET.
- **Presence:** OCHA's records of which organizations work in which district ("Who does What Where"), from which we count food security and nutrition partners.
- **People reached** by food security and nutrition partners, where it is reported in usable form: Somalia in 2022–24 and Sudan in 2019–22.

We match all three to districts (Somalia) and localities (Sudan) by their official codes, and FEWS NET's mapping units to the same districts, giving 74 Somali districts over 33 FEWS NET periods and 192 Sudanese localities over 18 periods. A period runs from one FEWS NET map round to the next.

Framework

Let N_{dt} be the unobserved need in district d in period t. At the map round that opens period t, FEWS NET publishes its current map, its forecast for the period (F_{dt}, the share of the district's population forecast to be in Crisis or worse) and its aid flags. Aid A_{dt} is allocated during the period. The phase observed at the next round is $P_{d,t+1} = N_{d,t+1} - \theta A_{dt}$, and FEWS NET's aid flag is its claim that $N - P$ is at least one phase. We estimate three equations.

Allocation. Does aid follow the forecast?

$$A_{dt} = \beta F_{dt} + \gamma C_{dt} + \rho A_{d,t-1} + \mu_d + \lambda_t + \varepsilon_{dt},$$

where C_{dt} is the current map. District effects μ_d remove persistent differences in need and access, and period effects λ_t remove the size of the country's envelope, so β asks whether a district gets more aid when FEWS NET forecasts it to be worse than usual. With district effects, lagged aid biases the estimates by roughly one over the number of periods (here 18–33); we also estimate the model in first differences, instrumenting the lagged change in aid with aid two periods back. As in Section 7, we split the forecast into the part predictable from the country, the season, rainfall, conflict and prices, and FEWS NET's own contribution. As a placebo, we add the forecast FEWS NET publishes at the *next* round, which allocations made during period t cannot have used.

Flags. Do FEWS NET's aid flags mark where aid went? We regress the share of a district's population under an aid flag on aid, with district and period effects and controls for the current phase. If the flag records aid holding phases down, it should rise when and where aid arrives.

Aid effects. Estimating θ needs aid that varies for reasons unrelated to need. We try a shift-share instrument: a district's share of the pooled fund's food and nutrition allocations in the first two years, times the fund's total allocation in each period, controlling for that share times the national Crisis share. The instrument is weak (first-stage F of 4 in Somalia and 10 in Sudan), and the estimates are imprecise and, if anything, of the wrong sign, which suggests that larger envelopes coincide with worse conditions in high-share districts. We report them in the replication files but draw no conclusions from them.

Results

Table A3 gives the main estimates. In Somalia, pooled-fund money follows FEWS NET's forecast. A district whose whole population is forecast in Crisis receives 1.10 more in asinh dollars (standard error 0.37) than when none of it is, and is 8 percentage points more likely to receive any (base: 12 percent of district-periods). The estimate barely changes with lagged aid or in first differences. People reached also rise with the forecast (1.69, standard error 0.81). But the money follows the part of the forecast that public information predicts (2.82, standard error 0.68), not FEWS NET's distinctive contribution (-0.01, standard error 0.32). And the placebo fails: the next round's forecast predicts this period's allocations almost as well (0.72, standard error 0.25). Money and forecasts track the same evolving conditions; within Somalia, there is no sign that FEWS NET's own information moves the money. In Sudan, none of the three measures of aid follows the forecast. The number of food security and nutrition partners present does not follow it significantly in either country.

FEWS NET's aid flags partly track where aid is. With district and period effects, each additional food security or nutrition partner in a district goes with a flag share 0.009 higher in Somalia (standard error 0.002) and 0.010 higher in Sudan (0.003). In Somalia, a one-standard-deviation rise in people reached per resident goes with a flag share 17 percentage points higher, against a mean of 20 percent. In Sudan, people reached does not predict the flag within localities. Pooled-fund money barely predicts it in either country. The flags are also sticky: in Sudan, 0.72 of a locality's flag share carries over to the next round. The flag is consistent with a standing judgment that aid is present, more than with a response to new aid.

These results qualify two parts of the paper. First, the country-level finding that money follows FEWS NET's distinctive information (Section 7) does not carry down to districts in the two countries we can examine: within Somalia the money that is located follows conditions everyone can see. Pooled funds are a small and atypical slice of aid, so this does not rule out a district-level response by the large agencies whose spending is not located. Second, the aid flags on which the benefit-cost calculation rests mark aid presence only loosely. Both point in the same direction as

Section 8: the case for FEWS NET in lives saved is weaker than its maps alone suggest.

Table A3: Aid and FEWS NET within Somalia and Sudan

Outcome	Regressor	Somalia	Sudan
Pooled-fund aid (asinh US$)	Forecast share in Crisis+	1.099***	-0.325

		(0.002)	(0.001)
Districts		74	192
FEWS NET periods		33	18

Notes: District (Somalia) or locality (Sudan) by FEWS NET period, 2014–2024 (Sudan from December 2018). All regressions include district and period effects (year effects in the annual regressions for people reached) and control for the share of the district mapped in Crisis or worse; flag regressions also control for the mean phase. Pooled-fund aid: food security, nutrition and multipurpose cash budgets of projects starting in the period (OCHA country-based pooled funds). Partners present: food security and nutrition organizations in OCHA's Who does What Where records. People reached: Somalia 2022–24 (Cash Working Group and OCHA records), Sudan 2019–22 (response plan monitoring). Standard errors clustered by district in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

H Replication

All data are public. The analysis is in Python, in the project's `code` directory.

- FEWS NET data: `01_fetch_fewsnet.py`, `07_build_panel.py`
- Official classifications: `04_fetch_ipc_ch.py`, `23_outcome_panel.py`
